ABSTRACT

Operation of spark-ignition (SI) engines with high levels of charge dilution through exhaust gas recirculation (EGR) achieves significant efficiency gains while maintaining stoichiometric operation for compatibility with three-way catalysts. Dilution levels, however, are limited by cyclic variability including significant numbers of misfires that becomes significant with increasing dilution. This variability has been shown to have both stochastic and deterministic components. Stochastic effects include turbulence, mixing variations, and the like, while the deterministic effect is primarily due to the nonlinear dependence of flame propagation rates and ignition characteristics on the charge composition, which is influenced by the composition of residual gases from prior cycles.

The dynamics of operation with an external EGR loop differ substantially from those of dilute operation without external recirculation, both in time-scale and cylinder-synchronization effects, especially when misfires are encountered. This paper examines these differences and the implications for prior-cycle-based control strategies.

INTRODUCTION

Market and regulatory pressures continue to mandate significant increases in vehicle fuel economy to reduce petroleum use and CO₂ emissions, and meeting this goal while also continuing to reduce emissions of traditional pollutants is a significant challenge. Increasing engine efficiency while maintaining emissions performance is a necessary component of any solution, and an approach which has gained widespread adoption in the market is the combination of engine downsizing with gasoline direct injection (GDI) and turbocharging utilized to maintain high torque output [1,2,3,4,5,6]. This strategy shifts operation on the regulatory drive cycles into higher-efficiency regions of the engine's speed-load map, while boosting specific load capacity to maintain acceptable vehicle acceleration performance. This approach has proven effective, but there are obstacles to further increasing the level of downsizing [2].

Engine downsizing is limited by multiple factors, including the occurrence of end-gas knock at high loads and sporadic "super knock" events brought on by low-speed pre-ignition (LSPI) events at very high loads [8,9,10,11], which can cause significant engine damage. In order to avoid end-gas knock, the compression ratio of the engine is limited, and spark timing must be retarded from the optimal combustion phasing at high loads, reducing the thermodynamic efficiency of the engine. Additionally, the higher exhaust temperatures caused by the late combustion phasing require that fuel enrichment be used

to protect the turbocharger, causing greater fuel efficiency penalties. The resulting operating conditions, with high cylinder pressures from boost and compression, along with late spark timing, allow for the occurrence of LSPI. The combination of these factors limits the compression ratio and boost that can be applied to increase efficiency and performance in downsized engines.

The addition of cooled EGR is a potential pathway to mitigating these effects. Alger, et al. [12] demonstrated that the knock-reduction effect of EGR is such that each 1% increase is equivalent to an increase of 0.5 in fuel octane number. This allows for more optimal spark timing, shifting combustion phasing towards a higher-efficiency point and reducing the time available for pre-ignition to occur. Charge dilution through EGR and earlier combustion phasing also reduce exhaust temperatures, mitigating the need for protective fuel enrichment. Pumping losses can also be decreased due to reduced throttling of the engine. These efficiency-enabling effects of EGR for downsized GDI engines were noted by Alger, et al. [13]. Cycle simulations by Prazul, et al. [14] also indicate the potential for brake thermal efficiency (BTE) of over 40% in light-duty engines using this strategy, while yielding very low engine-out NO_x emissions. Lean operation offers similar benefits, as well as improved thermodynamic cycle efficiency gains due to increased specific heat ratios, though it also requires the use of lean-NO_x aftertreatment and does not

Symbol-sequence statistics analysis finds order in chaos

ACCOMPLISHMENTS (2/6)

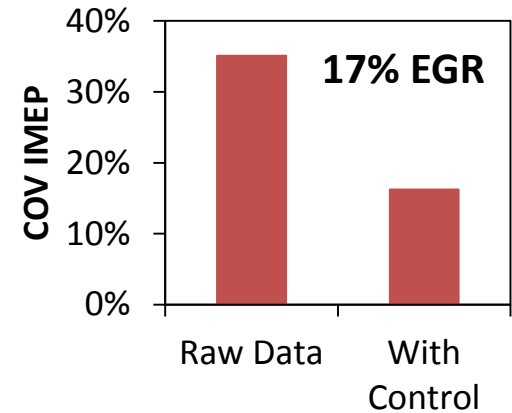

- Symbolization of chaotic time series data
 - Discretize data and identify patterns of recurring sequences
 - Enables automated identification of recurring, non-random trajectories
 - Robust even for low-quality or noisy input data
- Developed method of optimizing symbolization parameters for control purposes using modified Shannon entropy

Effective control would enable operation at the “edge of stability”

- Estimation of potential controller effectiveness:
 - Identify cycles that are part of frequently occurring patterns in symbol sequence analysis
 - Remove these cycles and recalculate statistics such as COV and mean IMEP based on “filtered” data
- Effective controls will yield higher thermal efficiency and reduced COV

ACCOMPLISHMENTS (3/6)

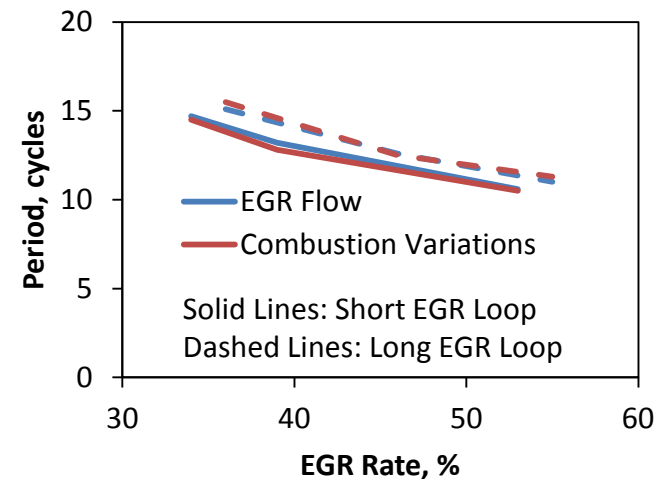

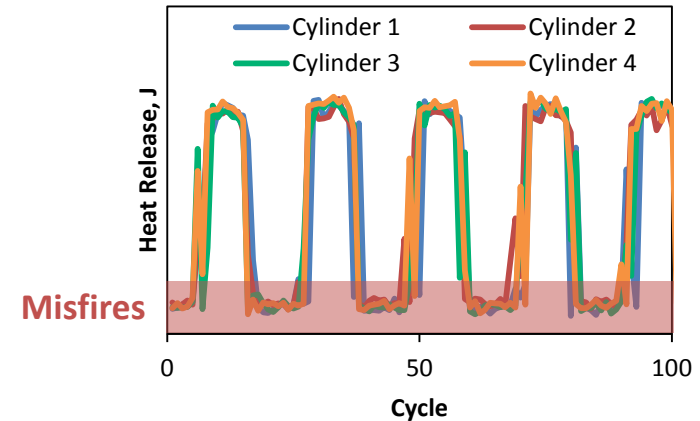

Indicates that symbol sequence analysis methods are well-suited for use in active controls to reduce COV and enable operation at the edge of stability

Long time-constant combustion instabilities were also found to occur with high-EGR operation

ACCOMPLISHMENTS (4/6)

- Combustion instabilities at very high EGR rates have unique structure
 - Alternates between high-quality combustion and misfires
 - Long time-scale (~ 10 s of cycles) variations in addition to previously observed short time-scale (~ 1 cycle) effects
- Varied EGR loop length
 - Period of combustion variations tracks closely with calculated EGR flow time
- Operated engine at extreme EGR levels to elucidate effects
 - Misfires are easier to detect than subtle changes

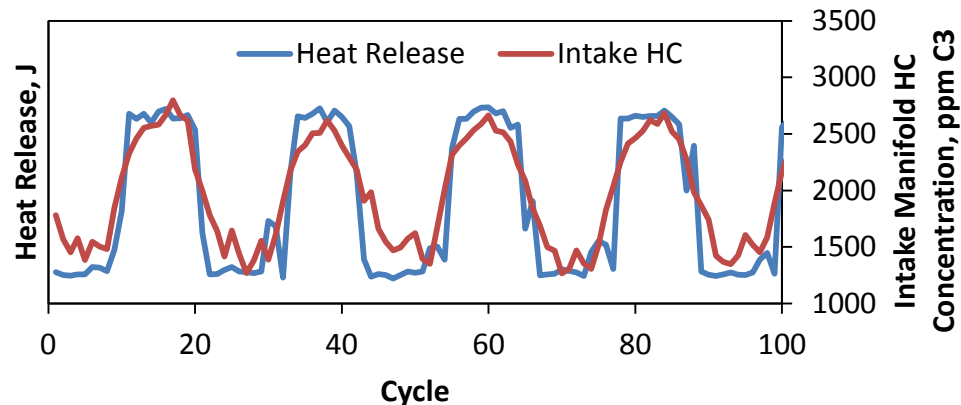

Same physical transport phenomena are present for more moderate EGR rates without misfires

Long-period instabilities are driven by EGR flow recirculation time

ACCOMPLISHMENTS (5/6)

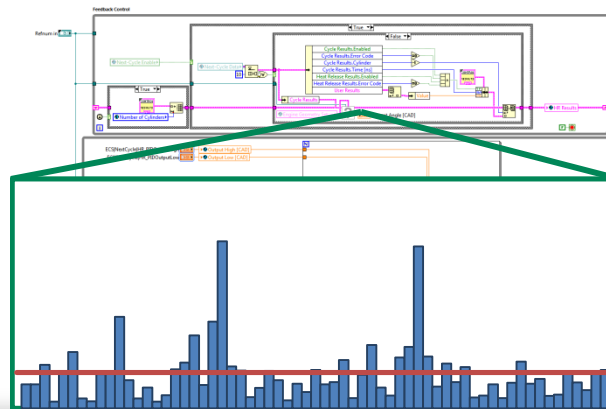

- External EGR loop feedback dominates over internal residuals
 - Period of oscillations (~ 1 s) is due to flow through EGR loop
 - Recirculated exhaust from misfire cycles provides extra fuel and air
 - Recirculated exhaust from high-energy cycles provides only inert diluent
- Intake HC concentration measurement verifies that EGR composition is the feedback mechanism

Next-cycle control being implemented: on-track to meet Q3 milestone

ACCOMPLISHMENTS (6/6)

- Automatic cylinder-to-cylinder balancing
 - Cycle cumulative heat release (via fuel mass)
 - Combustion phasing (CA50, via spark timing)
 - Functionality demonstrated in March 2014
- Next-cycle controls to reduce COV
 - Use symbolic analysis to detect impending undesirable dynamical trajectories based on prior-cycle results
 - Adjust fuel quantity to push system back to stable operation
 - Include EGR flow rate effects

Symbol sequence analysis method

TECHNICAL BACKUP 3

- Procedure:
 - Partition time series data into discrete bins
 - Consider sequences of a specified number of cycles
 - Identify patterns of sequences that recur frequently
- Advantage: algorithmically identify recurring, non-random patterns in noisy data

Partitioning example: in this case, data are discretized into binary partitions (0,1). More partitions can be used for higher resolution.

Symbol sequence histogram using 2 partitions and sequence length of 6 (optimal for this data). Red line indicates expected value for random data.

Modified Shannon entropy allows optimization of parameters for symbolic analysis

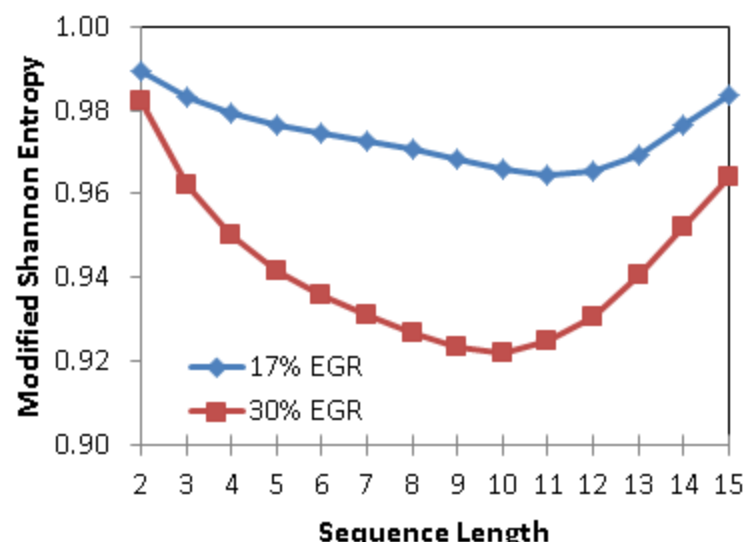

TECHNICAL BACKUP 4

- Modified Shannon entropy
 - Measure of information availability
 - Minimum corresponds to greatest determinism

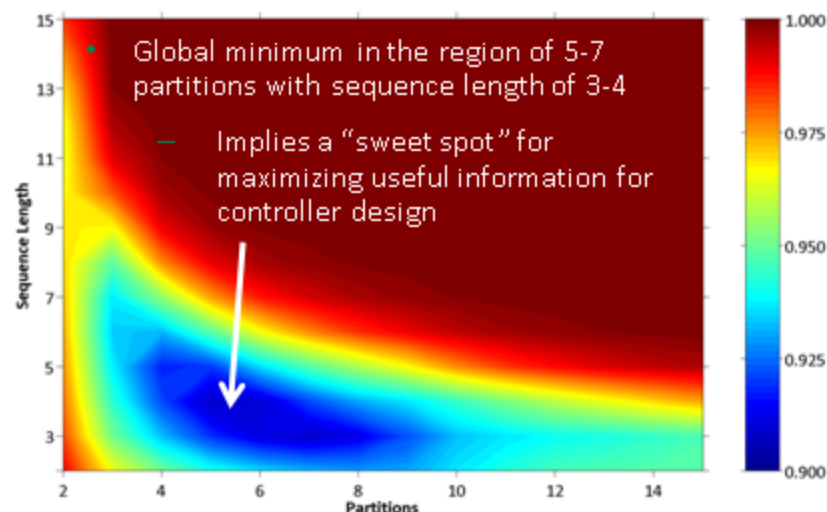

$$H_{s,m} = -\frac{1}{\log n_{seq}} \sum_k p_k \log p_k$$

n_{seq} = # of sequences

p_k = probability of sequence k occurring

Modified Shannon entropy variation with sequence length using 2 partitions

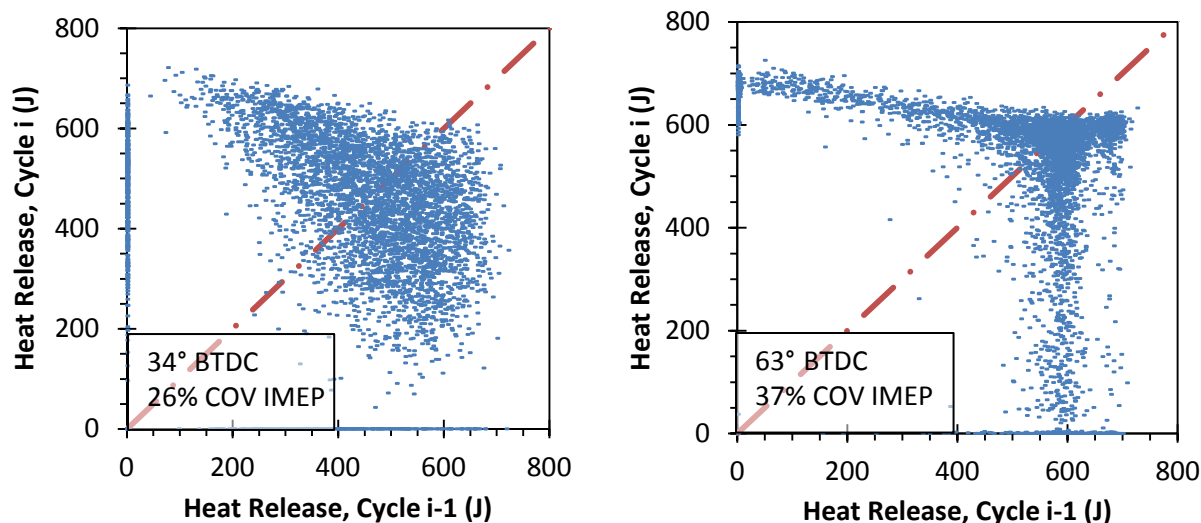

Modified Shannon entropy variation with number of partitions and sequence length

Ignition timing affects COV qualitatively

TECHNICAL BACKUP 5

- For retarded timing, high degree of spread in heat release is evident (many partial burns)
- More advanced timing tightens up the map and yields higher average BMEP, at the cost of additional misfires

Heat release return maps of cycle i vs. cycle i-1. Time asymmetry (about 45 diagonal) indicates determinism.

Engine operation at nominal 2000 rpm, 4 bar BMEP operation with 22% EGR and ignition timings of 34 and 63 BTDC.

Zones of stable and unstable operation in lean mixtures. The vertical axis indicates spark advance from TDC.
