The following discussion for Alternative 3 describes mining activities and their potential impacts on the site groundwater hydrology through the five phases of mining and closure. In some cases, phases are combined in the discussion because of the similarities in effects between sequential phases. The 3-D hydrologic analysis was performed with and without two specific mitigations (partial grouting and bulkheads). The effectiveness of grouting, installing bulkheads, and leaving barrier pillars with limited constructed bulkheads at access openings, and other possible mitigations, such as increased buffer zones between Rock Lake and the Rock Lake Fault, are discussed in section 3.10.4.3.6, *Effectiveness of Agencies' Proposed Monitoring and Mitigation*.

In general, the effects on the groundwater hydrology and related changes in stream baseflow would gradually increase through the Construction, and Operations Phases, as mine inflow increased due to increased mine void volume. Also, because of the low overall permeability of the bedrock, the groundwater system would be somewhat slow to respond to dewatering. Impacts on groundwater hydrology, as indicated by drawdown and related changes in stream baseflow are predicted to reach a maximum after mining ceased (in the Post-Closure Phase) and then slowly recover, reaching steady state conditions 1,150 to 1,300 years after mining ended.

3.10.4.3.1 Evaluation through Operations Phases

Mine Area

The two numerical models were used to approximate where and to what degree groundwater drawdown could occur, and to estimate changes in baseflow for drainages flowing from the area to be mined. The 3D model was configured to simulate the location of mine void and adits proposed in Alternative 3.

Mine and Adit Inflows

As mining activity progressed through the Evaluation, Construction, and Operations Phases, the average mine inflow would increase with predicted short-term spikes in flow as new adits and mine areas were opened (Figure 71). At full build out, the 2D numerical groundwater model predicted that the total steady state inflow to the mine and adits would be about 450 gpm (for the fault scenario, as defined in the 2D model). The 3D model provides considerable detail concerning predicted inflows during the various phases of mining, providing both average and stabilized dewatering rates. The dewatering rate at full mine build out during the 22-year life of mine (Evaluation through Operations Phases) is predicted by the 3D model to be about 370 gpm, with possible short-term inflow peaks of nearly 800 gpm during the mine Construction Phase (Figure 71). The short-term peak of 800 gpm assumes instantaneous development of two new adits and therefore over-estimates peak inflows.

Blasting during development of the adits and mine void and the presence of a mine void may result in stress redistribution that could affect local groundwater flow in fractures around the mine and adits. The stress redistribution may open some fractures and close others, depending on the actual stress regime. It is unlikely this would result in a change in the steady state inflows to the mine and adits. It is possible that changes to the fracture network resulting from the stress redistribution could affect (increase or decrease) drawdown beneath local areas and alter inflow to specific portions of the mine void and adits, but it is not possible to predict if or where this may occur.

Groundwater Drawdown

Both the 2D and 3D models provided estimates of drawdown during various phases of mining (ERO Resources Corp. 2009 and Geomatrix 2011a, respectively). The accuracy of the 2D model drawdown prediction is limited by the various assumptions described in the *Final Hydrogeology Technical Report* (ERO Resources Corp. 2009). Because the 3D model was able to include a more representative simulation of the known geologic structure, the 3D model's predicted extent of drawdown is considered to be more accurate than that of the 2D model.

The 3D model predicted that groundwater drawdown would be greatest along the trend of the adits, ranging between 10 and greater than 500 feet by the end of the Operations Phase. The greatest drawdown would occur along fault and fracture trends (generally northwest-southeast) that are intersected by the mine and adits. Near the mine void, the 3D model predicted that without mitigation, drawdown would generally be between 10 and greater than 100 feet, with an area between 100 and 500 feet in the upper portion of Rock Creek, upstream of Rock Lake. Drawdown exceeding 10 feet and less than 100 feet would extend about 1 mile from the mine and adits along the Rock Lake Fault, Libby Lakes fault, and Snowshoe fault (Geomatrix 2011a).

The pressure data collected from a piezometer at PR5220 in the Libby Adit provides some insight as to how groundwater levels may respond to dewatering, in comparison to the 3D model-predicted drawdown. As described in Section 3.10.3.1.1, *Site Hydrogeology,* water pressure was measured for 1 year in a piezometer located about 1,330 vertical feet from the surface. Because pre-dewatering data are not available, the amount of drawdown due to dewatering of the Libby Adit cannot specifically be determined. The 3D model predicted that the maximum drawdown in the vicinity of the eastern (shallower) half of the Libby and adjacent adits would be between 100 and 500 feet. If the potentiometric surface was at or near the ground surface before dewatering, then 440 feet of drawdown could have occurred as a result of the recent Libby Adit dewatering. Libby Creek may be acting as a fixed head boundary, supplying water to the ongoing dewatering of the Libby Adit, and preventing any additional drawdown. A fixed head boundary is one in which the potentiometric head or water table is held constant by some external force (a source of water) such as a river or lake. The calculated 440 feet of actual drawdown is a maximum possible value, because the elevation of the potentiometric surface before dewatering is unknown, the maximum possible drawdown value suggests that the 3D model predictions are a reasonable estimate of possible drawdown in the Libby Adit area.

Applying this information to other areas, the apparent hydraulic connection between the Libby Creek drainage and the adit via fractures 1,330 feet below the ground surface confirms that it is possible for mine dewatering to intercept surface water where faults or fractures have sufficient hydraulic conductivity and continuity. This observation supports the basic concepts developed in the numerical models. The specific location and frequency of occurrence of these structures are not currently known.

Changes in Baseflow

The effects of groundwater drawdown due to dewatering of the mine and adits are best expressed by estimating changes to baseflow (see section 3.8 for a discussion of baseflow). As part of the 2D and 3D numerical model calibration process, the model-predicted baseflow values were compared to measured flows considered to be baseflow in streams in the analysis area. In general, streamflow measurements were from gaging stations located on the periphery of the numerical model domain (Figure 67). Flow data from the upper reaches of the various streams are insufficient to quantify baseflow at these locations. Because the models were calibrated to flow data at the periphery of the model domain and to several other direct observations, the baseflow predictions at various locations along the streams are considered reasonable estimates of actual baseflow. There is considerable uncertainty regarding the annual variability of baseflow in the drainage reaches where baseflow has not been directly measured. The model results are also based on the assumption that the predicted baseflow is representative of a typical precipitation year. During a field review in September 2007, the agencies estimated that baseflow in the upper reaches of East Fork Rock Creek (above and just below Rock Lake) was similar to that predicted by the 2D and 3D numerical models. Precipitation records discussed in section 3.10.3.1.2, *Conceptual Hydrogeological Model of the Montanore Mine Area* indicated that the summer-fall period in 2007 was particularly dry.

Baseflow for the three periods (pre-mining, operations, and closure/post-closure) was modeled for locations along five streams (Libby, Ramsey, East Fork Rock, and Rock creeks, and East Fork Bull River) using the 2D numerical model (ERO Resources Corp. 2009). The same analysis was performed using the MMC 3D model, except slightly different locations along the streams were reported and the time periods used were also slightly different (Geomatrix 2011a). Geomatrix also included a location on the Bull River in its cumulative effects analysis. For consistency, the results of the baseflow analysis are reported for similar locations along three streams that originate in the analysis area (East Fork Rock Creek, East Fork Bull River, and Libby Creek); at or near the Forest Service gaging station, at the CMW boundary, and within the wilderness (Table 98). For two other creeks located farther from the mine and adits (Ramsey and Poorman), only predicted changes at the CMW boundary are reported (Figure 67).

Baseflow is predicted to start changing during the Evaluation and Construction Phases (Geomatrix 2011a). Because of the characteristics of the site groundwater hydrology, dewatering of the mine and adits would decrease groundwater levels (or cone of depression) that would slowly expand away from the mine openings, intercepting groundwater that would otherwise discharge to area streams. At the end of the Evaluation Phase, the 3D model predicted small reductions in baseflow of less than 3 percent in Libby Creek, East Fork Rock Creek, and East Fork Bull River. At the end of the Construction Phase, the baseflow reductions in Libby Creek increase to 12 percent at LB-300 and 9 percent at the CMW boundary, primarily due to adit dewatering. Baseflow reductions in the other streams are predicted to remain low through the Construction Phase. The Libby Adit was originally dewatered by NMC in late 1991 and allowed to reflood starting in late 1997. Once reflooded, water within the adit exited the adit via colluvium near the portal at an unknown flow rate until MMC reopened the adit and partially dewatered the Libby Adit beginning in 2008. Based on the historical information for the adit, it is inferred that the potentiometric head in the vicinity of the adit never fully recovered after the initial dewatering in 1991 and was farther drawn down with the subsequent MMC dewatering.

The 3D model used the calibrated heads as the initial head condition and apparently did not consider the actual head conditions in the vicinity of the adit. This situation may affect the predicted timing of impacts on the Libby Creek baseflow, but the magnitude of the changes would likely be unaffected. For example, the current adit dewatering has likely resulted in a reduction in Libby Creek baseflow upstream of the current point of discharge for the Water Treatment Plant but the effect is not detected because either the reduction is very small and/or there are insufficient pre-Libby Adit baseline data for comparison to current conditions.

Libby, Ramsey, and Poorman Creeks. The numerical model-predicted changes in baseflow in Libby and Ramsey creeks at the end of the Operations Phase would increase from the previous Phases (Table 98). The estimated baseflow reductions along Libby Creek would range from 14 percent in the wilderness to 22 percent at the CMW boundary. With MMC's modeled mitigation, the baseflow reductions would be slightly less (0.01 cfs) in the wilderness, but would otherwise be the same. Ramsey and Poorman creeks would have slightly less baseflow reduction at the CMW boundary with MMC's modeled mitigation.

Rock Creek and East Fork Rock Creek. The 3D model-predicted baseflow for the upper reaches of East Fork Rock Creek (above and below Rock Lake) is consistent with streamflow observed by the agencies during a September 2007 field review. In September 2007, no surface runoff was contributing to the stream. All of the observed flow was likely from deep bedrock groundwater discharge to the drainage. The flow rate out of Rock Lake was similar to the flow from East Fork Rock Creek above the lake. Additional monitoring proposed in Alternatives 3 and 4 (see Appendix C) would assess the source of flow in upper East Fork Rock Creek.

Table 98. Predicted Changes to Baseflow – End of Operations Phase.

Drainage and Location (Figure 67)	Model-Predicted Pre-mining Baseflow (cfs)	Without MMC's Modeled Mitigation			With MMC's Modeled Mitigation

cfs = cubic feet per second ("cfs" is the accepted unit for reporting streamflow. Because it is a large unit (1 cfs = 448.8 gpm), predicted changes in terms of cfs appear to be very precise (*i.e.* reported to 0.01 cfs). If the results were converted to gallons per minute, they would be reported to the nearest 5 gpm. Section 3.11.4.4.6. *Uncertainties Associated with Detecting Streamflow Changes due to Mine Activities* discusses streamflow variability and measurability.

With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

Source: Geomatrix 2011a.

The 3D model predicted that changes in baseflow at the end of mining due to mine dewatering would reduce the deeper groundwater contribution to East Fork Rock Creek above the lake by about 0.01 cfs or about 25 percent and 21 percent at the CMW boundary (Geomatrix 2011a) (Table 98). With MMC's modeled mitigation, the reduction would be slightly less at the CMW boundary.

East Fork Bull River. The same effects predicted in the upper reaches of East Fork Rock Creek are predicted by the two numerical models for the upper reaches of the East Fork Bull River drainage. The DEQ reported spring (SP-42) discharge in a drainage above St. Paul Lake near the trace of the Rock Lake Fault at about 200 feet lower in elevation than the spring (SP-41) observed in the East Fork Rock Creek drainage (McKay, pers. comm. 2007). During normal to dry years when winter snows have completely melted, deeper groundwater discharge may be the only source of water to St. Paul Lake during late summer to early fall. Spring SP-42 has not been confirmed to flow during the late summer baseflow period, so it is uncertain whether this spring contributes water to St. Paul Lake during the late summer season. Because St. Paul Lake is located on a relatively permeable glacial moraine, the lake is reported to be completely dry during extended periods of low or no precipitation. This indicates that the lake drains at a faster rate than input from groundwater during the late season, and the lake level is maintained by runoff from snowmelt early in the season.

The 3D model predicted the baseflow at the end of mining in the upper reaches of East Fork Bull River (below St. Paul Lake) would be reduced by about 0.05 cfs or by 17 percent (Geomatrix 2011a). The baseflow reductions would be the same with MMC's modeled mitigation during this phase.

Springs and Seeps

Based on the results of the numerical models, groundwater drawdown would occur around the mine as a result of dewatering of the mine void and adits. Flow from springs hydraulically connected to the deeper groundwater flow path would be reduced. Because springs located below an elevation of about 5,000 to 5,600 feet may derive their water from both shallow and deep groundwater flow paths at various ratios, it is not possible to predict the amount (if any) of flow reduction for any one spring. Some springs and seeps in the mine area have been inventoried, but the inventory has not yet identified the specific groundwater source for each spring or seep. The GDE monitoring described in Appendix C would require that specific analyses be performed to determine the source of water to specific springs.

Tailings Impoundment Area

Groundwater Drawdown and Changes in Baseflow

The Poorman Tailings Impoundment proposed in Alternative 3 would be between the Poorman Creek and Little Cherry Creek drainages. The available hydrogeologic data from the impoundment location indicate that the Poorman site is similar to the Little Cherry Creek site with the exception of having generally higher hydraulic conductivity than the Little Cherry Creek site. The effects of Alternative 3 would be similar to Alternative 2 (see section 3.10.4.2.1, *Evaluation through Operations Phases*), with the following differences:

- Based on available data, the Poorman site does not appear to have a buried channel, as does the Little Cherry Creek site, which reduces the concern of having a very deep, high hydraulic conductivity conduit beneath an impoundment that could become a preferential flow path for seepage from the impoundment.
- The Poorman Impoundment would be located directly upslope from Libby Creek. Consequently, the predominant groundwater flow direction from beneath the impoundment is to the east toward Libby Creek, rather than toward the much smaller Poorman Creek.

A pumpback well system would be installed downgradient of the impoundment and designed to capture all seepage from the impoundment that was not collected by the underdrain system. The pumpback well system would consist of a series of groundwater extraction wells designed to provide 100 percent capture of all groundwater moving from beneath the footprint of the impoundment. A preliminary pumping well system has been designed, based on existing site data, that has 16 extraction wells pumping at a combined rate of 247 gpm (Geomatrix 2010c). Geomatrix constructed a 3D groundwater model of the Poorman Impoundment Site to assist in design of the system. To establish full capture of the impoundment seepage, a drawdown cone would be created by the 16 extraction wells. Water levels from north of Ramsey Creek to north of Little Cherry Creek are predicted to be reduced (Figure 73). As a result of lower groundwater levels, the model predicted that operation of the pumpback well system would reduce baseflow in Poorman Creek by 0.18 cfs (81 gpm), Little Cherry Creek by 0.04 cfs (18 gpm), and in Libby Creek downstream of the confluence of Little Cherry Creek by 0.55 cfs (247 gpm). During the Operations Phase, water removed by the pumpback well system would be pumped to the impoundment for use in the mill.

The 3D model for the pumpback well system included an apparent subsurface bedrock ridge between the Little Cherry Creek and Poorman Creek watersheds. The low permeability bedrock ridge appears to separate groundwater flow between the watershed of Little Cherry Creek from those of Drainages 5 and 10 in the Poorman Impoundment Site (Chen Northern 1989). The bedrock ridge and resulting groundwater divide were interpreted from a resistivity survey performed on behalf of NMC and from drill logs, as interpreted by Klohn Crippen (2005). All available geologic and hydrogeologic data from the Little Cherry Creek and in the Poorman Impoundment areas were reviewed and discussed in detail by NewFields (2014a). NewFields concluded that the bedrock ridge would limit drawdown in the Little Cherry Creek watershed, but drawdown could still extend between watersheds unless the bedrock ridge provided a complete barrier to cross-boundary groundwater flow. According to NewFields (2014a), perched groundwater conditions occur beneath most wetlands in the Little Cherry Creek and Poorman impoundment areas and the hydrologic support for the wetlands appears to be direct precipitation and upgradient runoff water that infiltrates into the subsurface. NewFields concluded the operation of the pumpback wells would have little or no effect on most wetlands in the Little Cherry Creek watershed. If NewFields' interpretation proved to be accurate, it is likely that groundwater drawdown from pumping in the Poorman Impoundment Site would have limited effect on surface resources in the Little Cherry Creek drainage. The pumping rate required to capture all seepage would potentially be lower without recharge from the Little Cherry Creek watershed. Because geologic and hydrologic data from the area between the Little Cherry Creek and Poorman drainages are limited, they are not sufficient to eliminate the possibility of the pumpback well system adversely affecting surface resources, particularly groundwater-supported wetlands.

Additional subsurface data, such as aquifer pumping tests, from this area would be collected during the final design process of the Poorman Impoundment (see section 2.5.2.5.3, *Final Tailings Impoundment Design Process* in Chapter 2 and Appendix C). Site data to be collected would include an assessment of artesian pressures and their potential influence on impoundment stability, an assessment of a subsurface bedrock ridge between Little Cherry Creek and the effect it may have on pumpback well performance, aquifer pumping tests to refine the impoundment groundwater model and update the pumpback well design, and site geology to identify conditions such as preferential pathways that may influence seepage collection system, the pumpback well system, or impoundment stability. MMC also would complete aquifer testing at the Poorman Impoundment Site and finalize the design of the pumpback well system. After the system was designed, at least seven groundwater monitoring wells would be installed downgradient of the pumpback wells before construction of any of the impoundment facilities (see Figure C-7 in Appendix C). At least four of these wells would be constructed as nested pairs to monitor both shallow and deeper flow paths from the impoundment. The wells would be located so that the cross-sectional area below the impoundment was adequately covered by the monitoring wells. If any preferential flow paths were encountered during the construction of the impoundment or installation of monitoring wells, they would be monitored independently. The installation of pairs of nested wells is intended to monitor a reasonable vertical thickness of the saturated zone. These data would be used to confirm the geophysical results and the MMC's hydrogeologic interpretation. The 3D model would be rerun to evaluate the site conditions with the additional data. MMC would update the pumpback well design and analysis using the additional data, with a focus on minimizing drawdown north of impoundment.

In Alternative 2, MMC indicated make-up water may be necessary (see Table 14 in Chapter 2). For analysis purposes, the agencies identified a possible location for alluvial groundwater wells to supply make-up water to the mine, should mine inflow and water from the pumpback well system be inadequate for process purposes.

Section 2.5.4.3, *Water Use and Management* discusses a different water management approach for Alternatives 3 and 4. To provide adequate water for ore processing when Libby Creek water could not be used beneficially (whenever Libby Creek flow at LB-2000 was less than 40 cfs), MMC would, under Alternative 3, install an infiltration gallery along Libby Creek and divert up to 760 gpm of water during periods of high flow (April through July). The infiltration gallery would be along Libby Creek northeast of the Poorman Tailings Impoundment (Figure 26). The amount of make-up water required would depend on mine inflows, water production from tailings impoundment pumpback wells, and precipitation at the impoundment site. MMC would not withdraw any water for use whenever flows at the point of withdrawal were equal to or less than 40 cfs. Water rights are discussed in detail in section 2.5.4.3.2, *Water Rights* and section 3.12, *Water Rights*.

Groundwater withdrawals from Libby Creek alluvium would decrease groundwater level near the infiltration gallery while the gallery was in operation. Because of the relatively high hydraulic conductivity of the alluvium and the hydraulic connection with the active stream, groundwater levels in the alluvium is expected to fully recover between periods of pumping. Groundwater levels downgradient of the infiltration gallery would decrease while diversions were made. Appropriately designed, located and operated infiltration gallery providing up to 760 gpm would not substantially reduce upgradient alluvial groundwater levels. If the infiltration gallery were located in the vicinity of the proposed pumpback well system, the infiltration gallery may increase the area and magnitude of the predicted drawdown cone, when in operation.

Springs and Seeps

Numerous springs were identified in the area surrounding the Poorman Impoundment Site (Figure 70). Thirteen known springs are within the Alternative 3 impoundment disturbance area; five other springs would be outside of the disturbance area, but may be affected by the pumpback well system. As in Alternative 2, it is possible that the increase in hydraulic head over the springs by placement of saturated tailings would prevent future flow from the springs. Alternately, the springs could discharge to the underdrain system beneath the impoundment and be collected by the Seepage Collection System. The flow from springs located outside of the impoundment main dam may be affected by the pumpback well system. The predicted area of groundwater drawdown extended northward to Little Cherry Creek and beyond. Springs that could be affected by the pumpback well system are SP-10, 14, 15, 24 and 38 (Figure 73). Four of the springs potentially affected by the pumpback well system are north of a bedrock ridge that may limit drawdown effects north of it. Effects on wetlands are discussed in section 3.23, *Wetlands and Other Waters of the U.S.*

LAD Area

Alternative 3 does not include the use of LAD for disposal of mine wastewater and groundwater in the LAD Areas would not be affected. The capacity of the Water Treatment Plant would be expanded in Alternatives 3 and 4. If there was the need to dispose of water from the tailings impoundment during the Operations Phase in excess of the water treatment system capacity, MMC would use enhanced evaporation techniques within the footprint of the impoundment.

3.10.4.3.2 Closure Phase

Mine Area

The Closure Phase would start at the end of mining (Year 22) and extend through completion of site reclamation (Year 30). The years discussed in this and other sections are used for analysis purposes, and may vary from actual mining phases. The modeling of MMC's modeled mitigation assumed the construction of bulkheads in the year mining ceased (Year 22) when mine closure would actually take several years to implement. In addition, the following discussion is based on the results of the 3D model that did not consider multiple plugs in the adit for water rights mitigation. During the Closure Phase, dewatering of the mine void and adits would cease, the adits would be plugged, and the voids would begin to fill with groundwater. Plugging of the adits during the Closure Phase would result in recovery of baseflow in the Libby, Ramsey, and Poorman watersheds, after reaching a maximum baseflow reduction soon after the adits were plugged (between Years 22 and 25). Groundwater levels in the mine area are not expected to recover during this phase because groundwater would continue to flow into the dewatered mine void. Groundwater levels in the mine area would continue to decrease as water continued to flow into the mine void. Changes to baseflow in the East Fork Rock Creek and East Fork Bull River would continue to decrease, reaching a maximum during the early Post-Closure Phase, with the exception of East Fork Rock Creek above Rock Lake that would reach a maximum reduction during the Closure Phase (Table 99).

In addition to the grouting mitigation analyzed for the Operations Phase, a second mitigation would be implemented during the Operations and Closure Phases. During the Operations Phase, MMC would leave one or more low permeability barrier pillars at appropriate locations within the mine void to compartmentalize the large void into smaller sections if necessary to minimize post-mining changes in East Fork Rock Creek and East Fork Bull River streamflow and water quality.

If pillars were left in place, concrete bulkheads would be constructed at any access opening through the barrier pillars. For the Closure and Post-Closure Phase analyses, the mitigated results assumed both grouting during the Operations Phase and the barrier pillars were in place after mining ceased. The process for determining the need for barrier pillars is discussed in Chapter 2 (see p. 137 for Evaluation Phase, p. 156 for Operations Phase, and p. 172 for Closure Phase).

Based on the 3D model simulation and not considering water rights mitigation, the portal area of the adits would be plugged soon after the Operations Phase ended (Year 22). drawdown would reach a maximum in the area above the adits between Years 22 and 25 and groundwater levels would begin recovering as the adits filled with water. Maximum baseflow reductions in Libby, Ramsey, and Poorman creeks are predicted to occur soon after the adits were plugged. As groundwater levels rose, the impact on baseflow in the Libby Ramsey, and Poorman watersheds would begin to decrease from the maximum soon after the adits were plugged. Table 98 provides predicted baseflow changes for Year 22 (end of Operations Phase) and Table 99 provides predicted baseflow changes for Year 25 (Closure Phase without multiple adit plugs). The trend of increasing water levels is predicted to continue until groundwater levels reached steady state in Year 1,172 without MMC's modeled mitigation (Table 102). Mitigation implemented during the Operations Phase (grouting and low permeability barriers) and at closure (bulkheads at access openings in the barriers (unmined ore); multiple adit plugs), would reduce impacts on baseflow slightly in all streams and may change the timing of maximum impact, as described in the footnotes to Table 100.

To avoid adversely affecting senior water rights in the Libby Creek and Ramsey Creek drainages, MMC would install plugs at the base of each adit soon after mining operations ceased. Because the adits would then be hydraulically isolated from the mine void, groundwater levels would begin to recover. Steady state groundwater conditions would occur in the Libby Creek and Ramsey Creek drainages within an estimated 10 to 20 years. The estimate is based on an inflow rate to the adits of 100 to 200 gpm to all three adits, the assumption that during 8 months of the year water would be pumped from the adit for water rights mitigation, and filling of the adits from the mine void to the ground surface. Actual length of time would depend on location of the initial plugs and adit inflow rate at Closure. The time to fill the adits could be reduced to a few years if MMC used water diverted from Libby Creek during high flows to fill the adits during the Closure Phase. Baseflow changes in Libby Creek and Ramsey Creek would be similar to those shown in Table 99, but the effects would decline more rapidly with multiple adit plugs. Multiple adit plugs would not affect predicted baseflow changes in the East Fork Rock Creek and East Fork Bull River shown in Table 99.

Tailings Impoundment Area

The effects at the tailings impoundment area are discussed in the following Post-Closure Phase.

Table 99. Predicted Changes to Baseflow – Closure Phase.

Drainage and Location (Figure 67)	Model-Predicted Pre-mining Baseflow (cfs)	Without MMC's Modeled Mitigation			With MMC's Modeled Mitigation

Effects shown do not include mitigation measures not provided in MMC's 3D model report such as increasing buffer zones or using multiple plugs in the adits during closure. Such mitigation would be evaluated after additional data were collected during the Evaluation Phase.

cfs = cubic feet per second ("cfs" is the accepted unit for reporting streamflow. Because it is a large unit (1 cfs = 448.8 gpm), predicted changes in terms of cfs appear to be very precise (*i.e.* reported to 0.01 cfs). If the results were converted to gallons per minute, they would be reported to the nearest 5 gpm. Section 3.11.4.4.6. *Uncertainties Associated with Detecting Streamflow Changes due to Mine Activities* discusses streamflow variability and measurability.

Baseflow changes reported for Year 25 for all locations.

With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

[§]Negative value represents reduction of baseflow to zero and loss of water from storage in Rock Lake without MMC's modeled mitigation. The baseflow change of -0.44 cfs would result from a change in baseflow of 0.29 cfs plus a reduction in lake storage at the rate of 0.15 cfs.

cfs = cubic feet per second ("cfs" is the accepted unit for reporting streamflow. Because it is a large unit (1 cfs = 448.8 gpm), predicted changes in terms of cfs appear to be very precise (*i.e.* reported to 0.01 cfs). If the results were converted to gallons per minute, they would be reported to the nearest 5 gpm. Section 3.11.4.4.6. *Uncertainties Associated with Detecting Streamflow Changes due to Mine Activities* discusses streamflow variability and measurability.

With and Without MMC's modeled mitigation - maximum model predicted baseflow reductions occur at Year 38 for the Rock Creek drainage and Year 52 for the East Fork Bull River drainage. East of the divide, the maximum model predicted baseflow reductions in the Libby Creek watershed would occur between Year 22 (as reported in Table 98) and Year 25 (as reported in Table 99). Baseflow changes for east slope watersheds in this table are for Year 38. Effects shown do not include mitigation measures not provided in MMC's 3D model report such as increasing buffer zones or using multiple plugs in the adits during closure. Such mitigation would be evaluated after additional data were collected during the Evaluation Phase.

With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

3.10.4.3.3 Post-Closure Phase

The 3D model predicted the effect of the agencies' mitigation would be most noticeable in the Post-Closure Phase. Table 101 summarizes the difference in effects with and without mitigation. The following sections describe effects predicted by the 3D model, with and without mitigation.

Mine Area

Groundwater Drawdown without Mitigation

The Post-Closure Phase would begin in about Year 31 after all active reclamation activities were completed. Without mitigation, the mine void would continue to fill with water and groundwater levels would begin to recover around the deepest part of the mine void. Groundwater levels above the shallow end of the mine void (south end) would continue to decline, as the deep end of the mine void filled with water. Maximum drawdown is predicted to occur about 30 years after mining, with a maximum drawdown of more than 1,000 feet over the mine void north of Rock Lake (Figure 72). Water levels over the mine void closest to Rock Lake (in mining block 18) are predicted to reach maximum drawdown in Year 38, or 16 years after mining ceased (Chart 15).

Geomatrix (2011a) reported that the 3D model predicted that without mitigation the mine void and adits would require 493 years (or Year 515) to fill to an elevation of 4,800 feet (Chart 15). MMC proposed to maintain a 500-foot buffer from Rock Lake, which has an elevation of 4,958 feet. Although the upper mine void elevation would be less than 500 feet below the lake's elevation, the mine void would be 500 feet laterally from the lake. The upper mine void elevation may be less than 4,800 feet with a 500-foot buffer (Figure 11). Much of the mine void would be substantially filled in less time, but as the mine void filled, the inflow rate would decrease, requiring a predicted 493 years to completely fill the mine void to an elevation of 4,800 feet.

Chart 15. Predicted Water Levels Above Mine Void over Mining Block 18 Near Rock Lake, Without Mitigation.

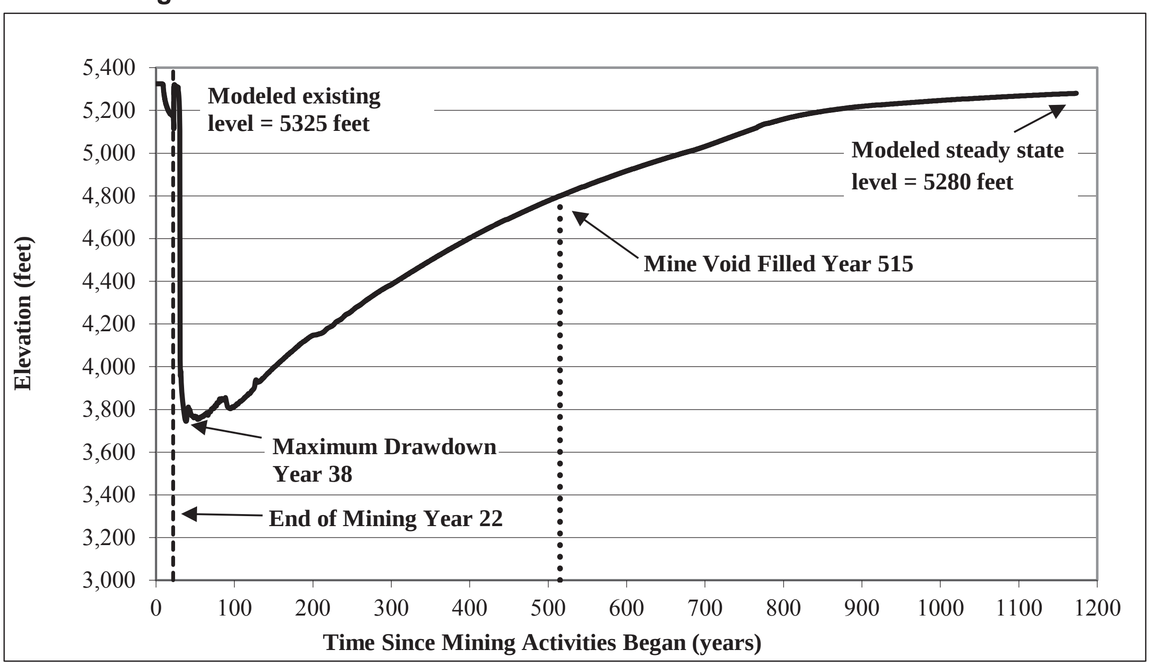

Table 101. Comparison of Groundwater Changes with and without Agencies' Mitigation.

Characteristic	Without Agencies' Mitigation	With Agencies' Mitigation
Mitigation		
Mine void barriers	None	Two or more barriers of unmined ore with bulkheads at access openings, if necessary
Mining buffer zones	500 feet from Rock Lake and 100 feet from Rock Lake Fault (Figure 11)	1,000 feet from Rock Lake and 300 feet from Rock Lake Fault (Figure 11)
Adit plugs	One plug near adit portal	Two or more plugs: one near mine void and one near adit portals
Grouting	None	Grout the sides of the three uppermost mine blocks and corresponding access ramps; additional grouting as necessary
3D Model Predictions		
Timing of maximum drawdown	16 years after mining for East Fork Rock Creek (Year 38) and 30 years after mining for East Fork Bull River(Year 52)	Similar to the without mitigation scenario
Timing of maximum drawdown in mining block 18 (closest to Rock Lake)	16 years after mining (Year 38)	2.8 years after mining (Year 25)
Timing of steady state conditions in groundwater levels over entire mine void	1,150 years after mining (Year 1,172)	1,300 years after mining (Year 1,322); multiple adit plugs not modeled but would increase time required to reach steady state
Timing of steady state conditions in groundwater levels over mining block 18 (closest to Rock Lake)	1,150 years after mining (Year 1,172) (Chart 15)	40 years after mining (Year 62)
Permanent effect on water levels overlying mining block 18	45 feet below pre-mine conditions (Chart 15)	Return to near pre-mine conditions
Timing of steady state conditions in groundwater levels over adits	130 years after mining	10 to 20 years after mining
Permanent effect on water levels overlying adits	Between 10 and 100 feet in some locations (Figure 74)	Not modeled; less than shown in Figure 74
Baseflow change in upper East Fork Rock Creek at maximum drawdown	0.29 cfs reduction at CMW boundary; 0.15 cfs loss of water from Rock Lake (Table 100)	0.17 cfs reduction at CMW boundary; no loss of water from Rock Lake (Table 100)
Baseflow change in upper East Fork Bull River at maximum drawdown	0.40 cfs reduction at CMW boundary (Table 100)	0.39 cfs reduction at CMW boundary (Table 100)
Baseflow change in upper East Fork Rock Creek at steady state	0.03 cfs reduction at CMW boundary (Table 102)	No change at CMW boundary (Table 102)
Baseflow change in East Fork Bull River at steady state	0.05 cfs increase at mouth (Table 102)	0.01 cfs reduction at mouth (Table 102)

With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.
cfs = cubic feet per second.

After the mine void and adits filled, water levels in fractures overlying the mine void and adits would continue to return to pre-mine conditions. Groundwater levels overlying the mine void and adits are predicted to reach equilibrium or steady state conditions in about Year 1,172 without MMC's modeled mitigation. Water levels are predicted without MMC's modeled mitigation to permanently remain greater than 100 feet below pre-mine conditions over portions of the mine void and between 500 and 1,000 feet in a small area 1,800 feet north of Rock Lake (Figure 74). Without mitigation, water levels overlying mining block 18 (the block closest to Rock Lake) are predicted to remain 45 feet below pre-mine conditions (Chart 15). Because of model uncertainties due to limited data, the time required for mine void refilling and the time required to reach steady state would be re-evaluated during the Evaluation Phase when more hydrogeologic data were available.

Groundwater Drawdown with Mitigation

With MMC's modeled mitigation as modified by the agencies, one or more barrier pillars would be left if necessary to minimize post-mining changes to East Fork Rock Creek and East Fork Bull River streamflow and water quality. The barrier pillars, if retained, would create two or more "compartments" within the mine void, with each filling at a rate controlled by the hydraulic conductivity of the surrounding rock. With the agencies' mitigation, groundwater levels above each compartment of the mine would continue to decline, as water filled each compartment created by the low permeability barriers. Because the hydraulic conductivity likely decreases with depth, the shallowest compartments of the mine void would fill sooner than the deeper sections. The shallowest compartments (those closest to Rock Lake) with mitigation would fill sooner than without mitigation. For example, lowest water table elevation over mining block 18 at the south end of the mine void is predicted, with MMC's modeled mitigation, to occur 2.8 years after closure, or 25 years after the onset of mining. With the agencies' mitigation of increased buffer of 1,000 feet, the highest mine void elevation would be several hundred feet deeper and the mining block closest to Rock Lake would fill within 10 to 20 years (Appendix G in Geomatrix 2011a). The agencies' mitigation in the mine area would reduce the maximum drawdown and the maximum change to baseflow.

As result of the water rights-related mitigation implemented during the Closure Phase, the adits would recover much sooner than predicted by the 3D model. Because the adits would be hydraulically isolated from the mine void, the adits would reflood and groundwater levels in the Libby, Ramsey, and Poorman creek drainages would reach steady state conditions independently from water levels over the mine void, within an estimated 10 to 20 years after operations ceased. The effect would be reduced to a few years if MMC used water diverted from Libby Creek during high flows to fill the adits during the Closure Phase. The residual drawdown in the Libby Creek drainage with the agencies' mitigation would be less than that shown in Figure 74.

With MMC's modeled mitigation, much less post-mining drawdown would be propagated to the water table on the south end of the mine void. Water levels closest to Rock Lake (overlying mining block 18) are predicted to return to near pre-mine conditions in about 40 years after mining (Appendix G in Geomatrix 2011a). Groundwater levels over the entire mine void are predicted to reach equilibrium or steady state in about Year 1,322 with MMC's modeled mitigation. Groundwater levels with MMC's modeled mitigation are predicted to take longer to reach steady state conditions because the rate of filling in the deeper sections would be slower than the average rate over the entire mine void without mitigation. Multiple adit plugs, which are a component of the agencies' mitigation that were not simulated in the model, would also increase the time to reach steady state conditions over the mine void because adit inflows would not fill the void. Because of model uncertainties due to limited data, the time required for mine void refilling and the time required to reach steady state would be re-evaluated during the Evaluation Phase when more hydrogeologic data were available.

Changes in Groundwater Storage

Assuming a reasonably range of storage values for the bedrock, such as those used in the 3D model, groundwater storage in the flooded mine void and adits would be significantly larger than groundwater stored in fractures in the same area before mining. If 120 million tons of ore and 3.2 million tons of waste rock were mined, the estimated increase in groundwater storage would be about 11.3 billion gallons or 34,600 acre feet of water without mitigation. With mitigation of increased buffers and barrier pillars, if necessary, the mine void and the increase in groundwater storage would be slightly smaller.

Changes in Baseflow

The predicted reductions presented in Table 102 would be permanent changes to pre-mining baseflow because groundwater levels would be at steady state and below pre-mine levels (Figure 74). Residual drawdown near the upgradient end of the mine is predicted to be greater along the Rock Lake, Libby Lake, and Snowshoe faults. As discussed in the Closure Phase section, a second mitigation of leaving barrier pillars, if necessary, would be designed using all available hydrologic data collected during mining and implemented during the Operations and Closure Phases.

The following discussion provides a summary of baseflow changes in the affected drainages during the Post-Closure Phase. Section 3.11.4.4.6, *Uncertainties Associated with Detecting Streamflow Changes due to Mine Activities* discusses streamflow variability and measurability.

The 3D model simulation of the Post Closure Phase indicates that effects on baseflow in the east slope drainages would reach a maximum during the Closure Phase and continue well into the Post-Closure Phase (hundreds of years without MMC's modeled mitigation). At steady state, the model predicted no impact on baseflows in the east slope drainages. The 3D model did not consider water rights mitigation that would greatly shorten the recovery time for the east slope groundwater levels, and therefore, stream baseflows. The adit plugging mitigation, as described in section 2.5.4.3.2, *Water Rights* and section 3.12, *Water Rights*, would hydraulically isolate the adits from the mine void and significantly reduce the refilling time of the adits. As a result, stream baseflow is expected to return to pre-mining rates within 10 to 20 years of the end of the Operations Phase, or within the first few years of the Post Closure Phase. The effect would be reduced to a few years if MMC used water diverted from Libby Creek during high flows to fill the adits during the Closure Phase.

As described previously, the groundwater levels above the mine void would continue to decline after dewatering ceased because the mine void would continue to draw from groundwater as it began to fill. As a result, the maximum drawdown in the area above the south end of the mine void would occur, without MMC's modeled mitigation, about 16 years after the adits were plugged (about Year 38) (Table 100). Starting some time before Year 38, the baseflow in upper East Fork Rock Creek (above Rock Lake, and at the outlet of Rock Lake in the vicinity of EFRC-200) would be reduced to zero. Without MMC's modeled mitigation, the 3D model also predicted that, in addition to 100 percent baseflow reduction to Rock Lake, the potentiometric surface

cfs = cubic feet per second ("cfs" is the accepted unit for reporting streamflow. Because it is a large unit (1 cfs = 448.8 gpm), predicted changes in terms of cfs appear to be very precise (*i.e.* reported to 0.01 cfs). If the results were converted to gallons per minute, they would be reported to the nearest 5 gpm. Section 3.11.4.4.6. *Uncertainties Associated with Detecting Streamflow Changes due to Mine Activities* discusses streamflow variability and measurability.
Steady state conditions predicted to occur at Year 1,172 without MMC's modeled mitigation and at Year 1,322 with MMC's modeled mitigation.
With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.
Source: Geomatrix 2011a.

would be sufficiently lowered to cause water in storage in Rock Lake to move into the groundwater system at the rate of 0.15 cfs. The water balance developed by Geomatrix (2011a) for Rock Lake indicates the lake receives water directly from the groundwater system, which is an indication that the lake is hydraulically connected to the groundwater system. Predicted impacts on Rock Lake are discussed in section 3.13.4, *Surface Water Hydrology*.

Because the baseflow reduction along East Fork Rock Creek would occur in the area overlying the predicted drawdown cone of depression (Figure 72), most if not all of the baseflow reduction would occur between EFRC-50 and upstream of Rock Creek Meadows. Based on the 3D model, groundwater discharges to the creek, and therefore baseflow, just upstream of the Rock Creek Meadows are predicted to be reduced by 0.29 cfs, without MMC's modeled mitigation.

As groundwater levels began to recover during the Post-Closure Phase (after Year 38), the changes in baseflow would decrease, reaching steady state by Year 1,172 without MMC's modeled mitigation. Because the 3D model predicted that groundwater levels would not recover to pre-mining levels, there would be a permanent loss of baseflow in upper East Fork Rock Creek (above Rock Lake) and a permanent reduction in baseflow in East Fork Rock Creek and Rock Creek (Table 102).

The primary predicted effect of MMC's modeled mitigation on the Rock Creek drainage during maximum baseflow reduction would be the elimination of the loss of water from storage in Rock Lake and a reduction in the change in baseflow in the vicinity of the lake by about half. Because groundwater levels would not recover to pre-mining levels, there would be permanent changes to baseflow in the Rock Creek drainage, but the effects would be smaller than those predicted without MMC's modeled mitigation.

Based on the results of both numerical models, reduced baseflow would persist during the Post-Closure Phase for a portion of the East Fork Bull River drainage until the mine void refilled with water and the regional potentiometric surface stabilized. As the regional potentiometric surface reached steady state conditions (Year 1,172 without MMC's modeled mitigation), both numerical models predict a slight increase in groundwater contribution to portions of the East Fork Bull River compared to pre-mining conditions (ERO Resources Corp. 2009 and Geomatrix 2011a). A change in groundwater flow path would occur because the mine void would interconnect the two watersheds, resulting in the diversion of groundwater from the East Fork Rock Creek to the East Fork Bull River drainage. The groundwater exchange rate between drainages is predicted to be very small (0.07 cfs). The only difference between the predictions of the two models is the location along East Fork Bull River where this may occur. The 3D model predicted the increase flow would occur mostly in the lower portion of the river below the CMW boundary, whereas the 2D model predicted the increased flow would occur in the upper reaches of the river within the wilderness.

As with the 2D model, the MMC 3D model also predicted, without MMC's modeled mitigation, that a potential for groundwater to flow from the East Fork Rock Creek watershed to the East Fork Bull River watershed via the mine void because of the void that would connect to the watersheds. Whether this occurred would depend on the location of sufficiently permeable faults and/or fractures between the distal end of the mine void and the Rock Lake Fault because the mine void would be located about 3,000 feet below the drainage. The 2D and 3D models showed that low permeability barriers within the completed mine void would control the level to which groundwater levels would recover, and therefore the direction of groundwater flow within the mine void.

There is uncertainty regarding the nature and extent of the Rock Lake Fault in the vicinity of East Fork Bull River. There is not sufficient mapping data to determine whether the near vertical normal Rock Lake Fault terminates within the East Fork Bull River, extends northward beyond the drainage, or transitions to a mapped thrust fault that extends down the drainage. This uncertainty in the 3D model simulation of the faults in this area would not impact any other part of the simulation or predictions of that model. The location of the discharge within East Fork Bull River is only relevant for the analysis of possible impacts on water quality from mine void water (see section 3.13.4.2.3, *Closure and Post-Closure Phases (Years 25+)*).

With MMC's modeled mitigation, the maximum reduction in baseflow along East Fork Bull River would be somewhat less (Table 100). The primary difference between the mitigated and unmitigated scenarios would be in the reversal of the hydraulic gradient at steady state, minimizing the flow of water from the mine void to East Fork Bull River. There would be a small permanent loss of baseflow to the river with MMC's modeled mitigation. The potential direction of post-mining groundwater flow direction within the mine void would be better defined using all hydrologic data collected during mining. The low permeability barrier design would be based on an analysis of these data.

Tailings Impoundment Area

At the beginning of the Closure Phase, the mill would cease operation and the tailings impoundment would no longer receive tailings. Because the mill would no longer use water from the impoundment, impoundment seepage collected by the seepage collection system and the pumpback well system would be treated at the Water Treatment Plant before discharging it. If the total rate collected by the two systems exceeded the capacity of the treatment system, MMC would pump any water in excess of the treatment system capacity back to the impoundment. Current Water Treatment Plant capacity is 500 gpm, which would be increased in Alternatives 3 and 4. Once all of the standing water was removed from the impoundment, the surface of the impoundment would be reclaimed. The seepage collection and pumpback well systems would continue to operate until flow from the impoundment met BHES Order limits or applicable nondegradation criteria of all receiving waters. As adjacent compliance wells met applicable standards, individual pumpback wells may be shut down and adjacent compliance wells still monitored. As long as the pumpback well system operated, its operation would reduce baseflow to Libby, Poorman, and Little Cherry Creek and reduce flow to springs and wetlands within the area of groundwater drawdown. When operating, the pumpback well system would pump at a rate necessary to maintain full capture of seepage from the impoundment. After flow from the impoundment met BHES Order limits or applicable nondegradation criteria of all receiving waters, operation of the seepage collection system and the pumpback wells would be terminated and the wells plugged and abandoned. Assuming pumpback wells operated at 250 gpm until all pumping ceased, groundwater levels would mostly recover in 13 years after pumping ceased with an estimated residual flow depletion to Libby Creek of 0.1 cfs (50 gpm) and fully recover in about 25 years (NewFields 2013a). Groundwater levels may recover sooner if pumping rates were reduced during the Closure Phase in response to tailings consolidation and impoundment reclamation. As groundwater levels recovered, springs that were buried by the impoundment, such as SP-26 and SP-28, may again flow, but into the impoundment's gravel underdrain system. Springs outside of the impoundment footprint that were affected by the pumpback wells would likely return to pre-mine conditions and may contribute to baseflow to channels outside of the impoundment.

3.10.4.3.4 Climate Change

The effects of climate change in combination with Alternative 3 would be the same as Alternative 2.

3.10.4.3.5 Groundwater Model Uncertainty

Both the 2D and 3D model reports include a discussion of the respective model's sensitivity to a range of hydrologic characteristics (ERO Resources Corp. 2009; Geomatrix 2011a). The sensitivity analysis for the 3D model indicates that varying hydraulic conductivity of the various layers by one order of magnitude (10 times) in either direction provides results that may be considered feasible, but the model calibration was poorer than for the selected values for hydraulic conductivity. The sensitivity analysis of varying hydraulic conductivity using the 3D model resulted in a range of mine inflows of 130 to 1,800 gpm. Based on historical and current inflow data from the Libby Adit, steady state mine inflows of 130 or 1,800 gpm are unlikely, indicating that the hydraulic conductivity values used in the calibrated model run provide a reasonable estimate of mine inflow, groundwater drawdown, and changes to baseflow within the constraints of other parameters used in the models.

Each model report discusses overall uncertainty of the respective model results. There is uncertainty associated with the hydraulic properties of the bedrock and faults; predictions of mine inflows and impacts on water resources are sensitive to permeability of major fault zones. With the data currently available, the model results provide a potential range of mine dewatering and pumping (in the case of the tailings impoundment model) rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models (mine area and tailings impoundment area) would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease.

To avoid confusion, this EIS uses the activity years reported in the 3D model report. The 3D model report assigns predictions to the nearest year, such as Year 22 or Year 1172. There is uncertainty as to the actual year any specific event would occur, particular for those events that would occur beyond end of mining.

In addition to model uncertainty, there is also the issue of measurability. The numerical models predict baseflow changes at various locations along streams draining the mine area, but the models do not consider what is possible to detect or measure. Other factors should be considered when reviewing and interpreting predicted baseflow. For example, baseflow at any one location along a stream may not be easily defined within the range of the model-predicted changes. Impacts from dewatering the mine and adits may be expressed in other ways, such as changing the elevation at which streams began to flow. Mine dewatering (and resultant groundwater drawdown) may cause this elevation to be lower in a drainage. Section 3.11.4.4.6. *Uncertainties Associated with Detecting Streamflow Changes due to Mine Activities* discusses streamflow variability and measurability.

3.10.4.3.6 Effectiveness of Agencies' Proposed Monitoring and Mitigation

Monitoring

Groundwater Levels

The most effective method for monitoring groundwater levels would be the installation of piezometers in the area overlying the ore body. This method is typically used to establish baseline groundwater conditions and monitor changes due to mine activities. Because the ore body is located within the CMW, the Forest Service did not include the installation of piezometers in the CMW in the agencies' alternatives. Drilling in the CMW would have required the use of helicopter supported drilling in an important grizzly bear corridor. To avoid affecting the bear from drilling in the CMW, the agencies developed a detailed underground monitoring program, provided in Appendix C. Underground monitoring would be effective if implemented as discussed in Appendix C.

In Alternatives 3 and 4, MMC would monitor groundwater level changes from numerous locations from within the mine and adits (Appendix C). This information would be effective in establishing seasonal and long-term trends resulting from mine dewatering, and in understanding the hydrogeology to be used in refining the 3D model. Because the underground piezometers would be installed after the dewatering process had started, this monitoring would not fully characterize pre-mining conditions. Also, once mining ended, the monitoring locations would not be accessible for collecting groundwater recovery data.

Groundwater levels downgradient of the tailings impoundment would be monitored both continuously using data loggers and by hand at an established frequency (Appendix C). Water quality monitoring in adjacent compliance wells also would be monitored. Monitoring data would be effective in establishing whether all groundwater flowing from beneath the impoundment was captured by the pumpback well system. Additional monitoring locations may be required if review of the initial monitoring network indicated that capture could not be confirmed due to inadequate data. This performance-based approach would require that the pumpback well system be modified, as necessary, to ensure that all tailings seepage was captured.

Changes in Spring Flow

The agencies would require that MMC collect flow data from springs in the area predicted by the groundwater model to be affected by groundwater drawdown due to mine dewatering. The monitoring would be initiated before the Evaluation Phase and would continue through the Operations and Closure Phases (Appendix C). Springs selected for flow measurement would be those that derive most or all of their water from bedrock sources, such as SP-41. Flow of the selected springs would be measured at least annually when accessible (typically early July through October), and others would be recorded continuously during the same time period.

With annual flow measurements of springs, many years of data collection would be required to identify potential spring flow decreases due to mine dewatering. Because of natural variability and flow measurement precision, it would be difficult to identify any flow changes other than large, obvious decreases in flow. To improve the effectiveness of spring flow measurements, the agencies would require that reference springs be identified in areas not expected to be affected by mine dewatering (Appendix C). The flow trends from the reference springs would be used to identify background trends that would otherwise complicate interpretation of flow measurements. Even with reference springs, it would be difficult to discern mine impacts from natural variability.

Changes in Stream Baseflow

The agencies would require that MMC collect flow data from stream reaches predicted to be affected by mine dewatering. The monitoring would be initiated before any additional dewatering of the Libby Adit for areas east of the Cabinet Mountains divide and before implementation of the Evaluation Phase for areas west of the divide. Monitoring would continue through the Operations and Closure Phases (Appendix C). Continuous data recorders would be used at some monitoring locations, where feasible, to obtain stream flow, particularly during periods of low flow. Because periods of high flow are dominated by surface water runoff, they are of less interest to this monitoring program. This monitoring requirement would be effective in obtaining year-to-year flow data, but because of natural variability, it would be less effective in identifying impacts on stream baseflow in any one year. Effectiveness would increase as data from multiple years were evaluated to establish long-term trends in baseflow.

Mitigation

Buffers

The 3D modeling was performed using buffers of 100 and 500 feet from the Rock Lake Fault and Rock Lake, respectively, and the data were reported to the agencies as requested. MMC did not report to the agencies the results of any additional modeling with larger buffers. Based on preliminary estimates of hydraulic properties of the bedrock and Rock Lake Fault, Evaluation Phase mining activities would be limited to within 300 feet of the Rock Lake Fault and 1,000 feet of Rock Lake to minimize the risk of high water inflow rates and resulting reduction in groundwater levels. To increase the effectiveness of this requirement, the agencies would re-evaluate the hydrogeology with the 3D model after obtaining additional hydraulic data from underground monitoring during the Evaluation Phase (as required in Appendix C). The evaluation would be used to increase or decrease the buffer zones between the Rock Lake Fault and Rock Lake, as necessary to reduce the risk of high mine inflows and excessive impacts. The agencies also would monitor underground mine development relative to the proscribed buffers (see section C.7.2 in Appendix C).

Grouting

For the purpose of analyzing the effects of possible mitigations, MMC simulated two options: grouting, during Operations Phase, of the sides of the three uppermost mine blocks and corresponding access ramps, as well as installing two 20-foot thick concrete pressure grouted wall bulkheads with a hydraulic conductivity of 1 x 10^{-9} cm/sec in two mining blocks across the mine void at Closure.

Because this mine would be of room-and-pillar design, grouting of fractures would be difficult, but technically feasible. Historically, grouting of fractures in the Libby Adit has been effective in reducing inflows, and MMC would be able to maintain grouting in the mine void and adits during construction and operations. With proper maintenance, grouting would be effective in reducing mine and adit inflows. Should certain threshold inflow rates be observed, as described in Appendix C, MMC would be required to report the conditions and the agencies would evaluate whether specific actions would be required, such as grouting. The effectiveness of grouting over the long term (i.e., 100 years or more) is uncertain. Limited information is available on the functionality of fracture grouting in mines once mining is completed, and there are no data on the design life of grout in an underground flooded environment. The uncertainty of constructed concrete bulkheads also would apply to fracture grouting.

Grouting during the Operations Phase, particularly in mining blocks closest to Rock Lake, would be a possible mitigation to reduce changes in baseflow in nearby watersheds, particularly East Fork Rock Creek. Implementation of this mitigation during the Operations Phase is predicted to result in minimal improvement in the predicted baseflow changes (Table 98). Other mitigation, such as increasing the buffer zones between the mine void and Rock Lake Fault, and the mine void and Rock Lake, may be more effective than MMC's modeled mitigation. In addition to increased buffers, additional grouting of other mining blocks would be possible, but the long-term effectiveness of this mitigation has not been established. Additional mitigation measures would be evaluated with the 3D model after obtaining additional hydraulic data from underground monitoring during the Evaluation Phase.

Barrier Pillars with Bulkheads at Access Openings

In the agencies' 2D model, a bulkhead was simulated to assess the effect of a low-permeability barrier on groundwater conditions at closure. In MMC's 3D model, a similar simulation was completed, with the bulkheads being described as concrete pressure-grouted wall bulkheads in two mining blocks in the mine at closure. The long-term effectiveness of constructed low permeability bulkheads is not documented as there are no available data on service life for time horizons commensurate with the Post-Closure modeling scenario. Current bulkhead design guidelines were developed principally to address water management problems in operating mines, and they emphasize design, construction and maintenance for ongoing operations. A common bulkhead design frequently involves a combination of a constructed barrier, usually made of concrete, along with grouting of the bedrock around the bulkhead perimeter. While bulkheads and grouting have quantifiable and measurable results, the success of these types of mitigations depends on the ability to monitor the bulkheads and to take remedial action, such as supplemental grouting, to stem any persistent inflows. Much of the information pertaining to the use of hydraulic barriers in underground mining comes from applications in operating coal mines (Harteis *et al.* 2008, Chekan 1985, Environmental Protection Agency 1977). There is limited information on functionality of hydraulic barriers once mining is completed, and there are no data on the design life of these structures. The agencies concluded that they cannot confirm the long-term effectiveness of constructed bulkheads across the entire mine void and their ability to maintain a very low hydraulic conductivity across the entire mine void over time. With constructed bulkheads across the entire mine void, baseflow may increase from the East Fork of Rock Creek drainage toward the East Fork of Bull River drainage as predicted by the 3D model. Werner (2014) describes the agencies' evaluation of the effectiveness of constructing bulkheads across the mine void in more detail.

As an alternative to constructed bulkheads with unknown long-term efficacy, the agencies propose to leave barrier pillars across the entire width of the deposit at strategic locations to divide the deposit into discrete compartments to minimize changes in pre-mining groundwater conditions, which would minimize movement of water between the watersheds of the East Fork Rock Creek and East Fork Bull River. There would be a limited number of access points through the barrier pillars for ore haulage, personnel and equipment access. At closure, bulkheads would be placed across these access points. The bulkheads would differ from those described in the modeling reports in that their dimensions would be on the order of feet rather than entire width of the mine void (up to 2,400 feet wide). Leaving barrier pillars overcomes some of the limitations associated with constructed bulkheads, such as long-term effectiveness (Werner 2014). Although a constructed bulkhead would be made of concrete and grout and a barrier pillar would be made of in-place unmined rock, they both would function in a similar manner to reduce the hydraulic conductivity between sections of the mine void. Consequently, the agencies considered the modeling of the bulkheads to be an equivalent simulation of the agencies' mitigation of leaving one or more barriers, if necessary, during the Operations Phase and constructing bulkheads at the access openings at closure.

Because the constructed concrete bulkheads would represent a relatively small proportion of the total bulkhead cross section that would mostly consist of unmined rock, the long-term effectiveness of the constructed bulkhead would be less of a concern, than if the entire mine void opening were plugged with a constructed bulkhead. The long-term effectiveness of constructed low permeability bulkheads is not documented as there are no available data on service life for the time horizon considered with the Post-Closure modeling scenario. The constructed bulkhead may begin to leak at some point in the future, but small increases in hydraulic conductivity as a result of leakage would not likely significantly increase the groundwater flow rate along the mine void. As water levels in the mine void recover on either side of a barrier, the pressure differential would decrease, reducing the flow rate through an intact barrier or through a partially failed constructed bulkhead. Because groundwater flow is proportional to both the hydraulic conductivity and groundwater pressure, groundwater flow through a barrier/bulkhead during the later stages of groundwater level recovery would decrease as the pressure differential decreases. Any increase in the hydraulic conductivity of the barrier/bulkhead due to small failures of a man-made bulkhead during the later stages of groundwater level recovery would be offset by decreases in the differential pressure. This would be particularly true because the man-made barriers would represent a relatively small proportion of the total mine void cross-sectional area.

The agencies' evaluation concluded that man-made concrete bulkheads within a larger barrier created by leaving unmined rock or pillars in place would likely provide the necessary mitigation during much of the groundwater level recovery period. Eventual failure of the constructed portion of the bulkhead would not likely result in significant increases in the total groundwater flow through the mine void.

By the fifth year of operations, MMC would assess the need for barrier pillars to minimize post-mining changes in East Fork Rock Creek and East Fork Bull River streamflow and water quality. If needed, MMC would submit a revised mine plan with one or more barrier pillars with constructed bulkheads at access openings to the agencies for approval. One or more barriers would be maintained underground, if necessary, after the plan's approval. Implementation of this mitigation would decrease the hydraulic head in the north end of the mine void and reduce the maximum baseflow changes at the CMW boundary along East Fork Rock Creek during the Post-Closure Phase from those predicted for the unmitigated baseflow changes. This mitigation is predicted to eliminate the loss of water from storage in Rock Lake during the same time period. The potential direction of post-mining groundwater flow direction within the mine void would be better defined using all hydrologic data collected during mining. The low permeability barrier design would be based on an analysis of these data to improve its effectiveness.

Multiple Adit Plugs

MMC proposed that a single water-retaining plug (bulkhead) would be installed in competent bedrock near the opening of each adit. In the agencies' alternatives, MMC would place two or more plugs in each of the three mine adits. The plugs would be located to isolate the adits hydraulically from the mine void and to ensure any groundwater tributary to Libby and Ramsey creeks would flow into the adits, and remain within the Libby Creek and Ramsey Creek watersheds during the period of groundwater recovery. Without multiple plugs, as simulated by the 3D model, a considerable amount of time (hundreds of years) would be required for the adits to resaturate because any water produced in the adits would flow downhill toward the mine void. A plug at the base of the adits would be effective in hydraulically isolating the adits from the mine void. Without these plugs, as simulated by the 3D model, a considerable amount of time (hundreds of years) would be required for the adits to resaturate because any water produced in the adits would flow downhill toward the mine void. Plugs would prevent adit inflow water from leaving the adits, and allow the adits to reach steady state conditions independently from water levels over the mine void, within an estimated 10 to 20 years after operations ceased. The effect would be reduced to a few years if MMC used water diverted from Libby Creek during high flows to fill the adits during the Closure Phase. Two or more plugs in each adit would provide additional confidence that the plugs would continue to be effective while groundwater levels recover beyond that provided a single plug. Multiple low permeability plugs within an adit would reduce the total groundwater pressure on the bottom plug by segmenting the open adit into compartments, increasing the overall effectiveness of the plugging approach. As groundwater levels recovered, both in the adits and the mine void, the differential pressure between compartments separated by a plug would decrease, which would decrease the potential for failure of a plug and decrease the potential for flow of groundwater through a plug, even if a plug partially failed.

Groundwater Pumpback Well System at Impoundment Site

A groundwater pumpback well system downgradient of the tailings impoundment can be an effective means of collecting seepage from the impoundment that may bypass the underdrain system (estimated to be about 25 gpm). To be effective, a pumpback system would have to be designed to accommodate likely heterogeneities in the groundwater system beneath and down-gradient of the impoundment and be properly monitored to make adjustments in well placement and pumping rates. The goal of a pumpback system would be to establish and maintain complete hydraulic capture of all groundwater moving downgradient from the impoundment, as confirmed by measuring water levels at strategically located monitoring wells. The actual performance of the capture system would be determined by monitoring water quality downgradient of the capture zone. Should water quality changes attributable to tailings seepage be observed, the pumpback well system would be adjusted to improve hydraulic capture.

3.10.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

3.10.4.4.1 Evaluation through Post-Closure Phases

Mine Area

Alternative 4 would have the same effects and uncertainties on groundwater levels and springs and seeps overlying the ore body and baseflow in East Fork Rock, Libby, Ramsey, and Poorman creeks and East Fork Bull River as Alternative 3 (section 3.10.4.3.1, *Evaluation through Operations Phases*). The effects of the Libby Adits would be the same as Alternative 3. The effect of make-up wells on groundwater levels in Alternative 4 would be the same as Alternative 2.

Tailings Impoundment Area

Numerous springs and seeps were identified in the area surrounding the Little Cherry Creek Impoundment Site (Figure 70) (Geomatrix 2006c, 2009b; Kline Environmental Research 2012). Springs SP-15, 23, and 24 would be covered by the impoundment, and a fourth spring (SP-10) would be covered by the Seepage Collection Pond. Two other springs would be in the disturbance area. Seeps in Little Cherry Creek also would be covered by the impoundment. A pumpback well system required to capture seepage not collected by the underdrain system would lower ground-water levels and reduce groundwater discharge to springs, seeps, and wetlands surrounding of the impoundment. Eleven known springs outside of the disturbance area may be affected by the pumpback well system. Operation of a pumpback well system may not affect water levels and six of the springs south of the Little Cherry Creek watershed because of an apparent subsurface bedrock ridge that separates groundwater flow between the watershed of Little Cherry Creek from those of Drainages 5 and 10 in the Poorman Impoundment Site (Chen Northern 1989). Additional subsurface data from this area would be collected during the final design process of the Little Cherry Creek Impoundment to confirm the geophysical results. A 3D model of the pumpback well system would be developed to evaluate the effect of the wells.

During final design, MMC would collect whatever data were necessary to develop a 3D model for a pumpback well system. The additional data would include investigation of a subsurface bedrock ridge that may exist between the Little Cherry Creek and Poorman Creek watersheds. The low permeability bedrock ridge may separate groundwater flow between the watershed of Little Cherry Creek from those of Drainages 5 and 10 in the Poorman Impoundment Site (Chen Northern 1989). If a ridge and hydrologic divide separates the two areas, it is unlikely that pumping in the Poorman Impoundment Site would affect groundwater levels in the Little Cherry Creek drainage. The pumping rate required to capture all seepage would potentially be lower without recharge from the watersheds of the drainages in the Poorman Impoundment Site, such as Drainages 5 and 10.

The amount of seepage collected by the seepage collection facilities may be increased compared to Alternative 2 by locating the Seepage Collection Pond with respect to the local geologic conditions. Geotechnical investigations at the Little Cherry Creek Impoundment Site were conducted on behalf of NMC between 1988 and 1990. NMC reported that bedrock is exposed in the Little Cherry Creek channel and bedrock extends about 800 feet downstream of the proposed Seepage Collection Dam (Morrison-Knudsen Engineers, Inc. 1990). Groundwater modeling conducted by MMC (Klohn Crippen 2005) and independently verified by the agencies (USDA Forest Service 2008) assumed that the fractured bedrock in the Little Cherry Creek drainage is the primary aquifer for groundwater flow at the site. The modeling indicated that any tailings seepage not intercepted by the seepage collection and pumpback well systems would likely discharge to the Little Cherry Creek watershed through the fractured bedrock aquifer (USDA Forest Service 2008). If not intercepted, some of the seepage may flow to Libby Creek via a buried channel beneath the impoundment site. Klohn Crippen (2005) estimated 80 percent of the existing groundwater flows toward Little Cherry Creek and 20 percent flows toward Libby Creek via the buried channel. Any tailings seepage is likely to follow existing groundwater flow paths. Consequently, siting the Seepage Collection Dam at or below the location where bedrock outcrops in the Little Cherry Creek drainage would increase the likelihood that the seepage would be collected by the dam. In Alternative 4, MMC would conduct additional geotechnical work near the Seepage Collection Dam during final design and site the dam lower in the drainage if technically feasible.

Other effects in the tailings impoundment area would be the same as Alternative 2. The potential impacts on Libby Creek alluvial groundwater from appropriations during high-flow periods would be the same for Alternatives 3 and 4.

LAD Areas

The use of LAD Areas is not proposed for Alternative 4 and groundwater in the LAD Areas would not be affected.

3.10.4.4.2 Climate Change

The effects of climate change in combination with Alternative 4 would be the same as Alternative 2.

3.10.4.5 Cumulative Effects

3.10.4.5.1 Past and Current Actions

The Heidelberg Adit is a horizontal tunnel that was constructed in the 1920s. The adit extends about 790 feet into a cliff face located along East Fork Rock Creek about 850 vertical feet below Rock Lake. Groundwater flow from the adit is reported to range from 45 to 135 gpm (Gurrieri 2001). During the agencies' September 2007 field review, flow from the adit was estimated to be 50 gpm and, because of dry conditions at the time of the site visit, this rate is considered to be baseflow from bedrock. Because flow data were apparently not collected before construction of this adit, it is not known if the adit outflow affected baseflow in nearby East Fork Rock Creek.

The Libby Adit was constructed between 1990 and 1991 by NMC and is about 14,000 feet long and slopes downward toward the ore body at a 6 percent slope. Groundwater inflow to the adit increased as the adit was driven, peaking at 239 gpm. The steady state flow from the adit was 150 gpm. Surface flow monitoring was insufficient to identify possible reductions in baseflow in Libby Creek. No groundwater piezometers were installed at the time the adit was constructed to identify changes in groundwater levels near the adit as result of dewatering.

3.10.4.5.2 Rock Creek Project

The two Montanore numerical groundwater models (2D and 3D) were used to assess the cumulative effects of the Montanore and Rock Creek mines. The approximate footprint of the Rock Creek Mine was used in both models. The models were used to predict the effects of simultaneous operation of the two mines by predicting the amount of drawdown in the region during the Post-Closure Phase and the resulting reduction in groundwater contribution to surface water.

The Montanore 3D numerical model predicted that the combined drawdown from the Rock Creek and Montanore mines would merge in a small area beneath the East Fork Bull River watershed (Figure 75). As a result, there would be a small incremental reduction in the baseflow (about 2 percent) to East Fork Bull River at the CMW boundary and a 1 percent decrease in baseflow at the mouth of East Fork Rock Creek as a result of a cumulative effect during the Post-Closure Phase (Table 103). The model predicted that most of the cumulative effect would occur in the lower reaches of the drainages. Streams in the Libby Creek watershed would not be cumulatively affected.

A Rock Creek 3D model prepared by Hydrometrics (2014) on behalf of Rock Creek Resources provided results specifically for the proposed Rock Creek Mine. The model simulation included more site specific detail concerning the mine, geologic structures, and mine operation than was available during preparation of the Montanore 3D for the same area. Adding the results from the Rock Creek Resources and Montanore models for the period of greatest drawdown, assuming these periods would occur at the same time for the two mines, the predicted cumulative baseflow impacts from the two mines would be 0.2 to 0.3 cfs greater in Rock Creek and East Fork Bull River than predicted by the cumulative analysis performed by Montanore.

In addition, during the period of maximum drawdown, based on the Montanore 3D model, the Montanore Mine is predicted, without mitigation, to reduce baseflow in East Fork Rock Creek at the CMW boundary by 0.29 cfs (100 percent of the predicted baseflow) and reduce storage in Rock Lake by 0.15 cfs (for a total "demand" of 0.44 cfs). The Rock Creek 3D model predicted a baseflow at the CMW boundary of 0.7 cfs compared to 0.29 cfs from the Montanore model. Because the Montanore model predicted a total "demand" from mine dewatering of 0.44 cfs, 0.15 cfs (0.44 minus 0.29 cfs) would come from Rock Lake storage. If the baseflow were greater than 0.44 cfs (as predicted by the Rock Creek 3D model), all of the Montanore "demand" would come from baseflow, rather than a combination of baseflow and lake storage. In such a scenario, cumulative baseflow reduction at the mouth of Rock Creek would be 0.15 cfs greater than what is reported in Table 103 because all of the Montanore "demand" would be met from baseflow, rather than lake storage.

3.10.4.5.3 Other Reasonably Foreseeable Actions

Two reasonably foreseeable mining operations, Libby Creek Ventures drilling plans, and the Wayup Mine would not affect groundwater conditions and would not have cumulative effect with the Montanore Project. No other reasonably foreseeable actions would have cumulative effects on groundwater flow.

3.10.4.6 Regulatory/Forest Plan Consistency

3.10.4.6.1 Organic Administration Act and Forest Service Locatable Minerals Regulations

The Forest Service is responsible for ensuring that mine operations on National Forest System lands comply with Forest Service locatable mineral regulations (36 CFR 228 Subpart A) for environmental protection. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest System surface resources. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8 because MMC did not propose to implement feasible measures to minimize adverse environmental impacts on surface resources. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would incorporate additional feasible measures to minimize adverse environmental impacts on National Forest System surface resources. The measures would include increasing mining buffer zones, installing multiple adit plugs at closure, grouting, and, if necessary, leaving mine void barriers. Using thickened tailings would reduce MMC's appropriation from the Libby Creek and minimize effects on Libby Creek streamflow. The agencies' alternatives expanded MMC's proposed monitoring plans and would include action levels on mine inflows and changes in surface water flow and lake levels that would trigger corrective measures to be implemented by MMC (see Appendix C).

3.10.4.6.2 Wilderness Act

All mine alternatives have the potential to indirectly affect wilderness qualities. Mitigation measures identified in Chapter 2 for Alternatives 3 and 4 and monitoring required for Alternatives 3 and 4 (Appendix C) would be implemented to minimize potential changes in wilderness character. Mitigation measures such as increasing the buffer zones near Rock Lake and the Rock Lake Fault, and the agencies' monitoring coupled with final design criteria submitted for the agencies' approval, would reduce the risk of subsidence and measurable hydrological indirect effects to the surface within the wilderness.

Table 103. Predicted Cumulative Changes to Baseflow – Post-Closure (Maximum Baseflow Change).

Drainage and Location (Figure 67)	Model-Predicted Pre-mining Baseflow (cfs)	Without MMC's Modeled Mitigation			With MMC's Modeled Mitigation[†]		
		Model-Predicted Baseflow (cfs)	Predicted Change in Baseflow (cfs)	Percent Change in Baseflow	Model-Predicted Baseflow (cfs)	Predicted Change in Baseflow (cfs)	Percent Change in Baseflow
Rock Creek and East Fork Rock Creek							
At mouth (RC-2000)	7.70	7.02	-0.68	-9%	7.51	-0.19	-2%
CMW Boundary (EFRC-200)	0.29	0.00 (-0.15)[§]	-0.29 (-0.44)[§]	-100%	0.12	-0.17	-59%
In CMW (EFRC-50)	0.04	0.00	-0.04	-100%	0.00	-0.04	-100%
East Fork Bull River							
At mouth (East Fork Bull River)	11.34	10.98	-0.36	-3%	10.99	-0.35	-3%
CMW Boundary (EFBR-500)	4.36	3.88	-0.48	-11%	3.91	-0.47	-11%
In CMW (EFBR-300)	0.29	0.00	-0.29	-100%	0.01	-0.28	-97%
Based on RCR's Model Results*							
Rock Creek at mouth (RC-2000)	7.8	6.7	-1.1	-14%			
East Fork Bull River at CMW Boundary (EFBR-500)	1.9	1.0	-0.9	-47%			
East Fork Bull River at mouth	10.4	9.6	-0.8	-8%			

[†]Geomatrix 2011a did not report cumulative effects with mitigation nor did it report Year 52 reductions for East Fork Bull River. The agencies determined the incremental unmitigated cumulative effect and added that effect on the direct mitigated effect.

[§]Negative value represents reduction of baseflow to zero and loss of water from storage in Rock Lake without MMC's modeled mitigation. The baseflow change of -0.44 cfs would result from a change in baseflow of 0.29 cfs plus a reduction in lake storage at the rate of 0.15 cfs.

[*]RCR did not model effects with mitigation.

cfs = cubic feet per second ("cfs" is the accepted unit for reporting streamflow. Because it is a large unit (1 cfs = 448.8 gpm), predicted changes in terms of cfs appear to be very precise (*i.e.* reported to 0.01 cfs). If the results were converted to gallons per minute, they would be reported to the nearest 5 gpm. Section 3.11.4.4.6. *Uncertainties Associated with Detecting Streamflow Changes due to Mine Activities* discusses streamflow variability and measurability.

With and without MMC's modeled mitigation - maximum model predicted baseflow reductions occur at Year 52 for East Fork Bull River, Year 38 for the Rock Creek drainage. Effects shown do not include mitigation measures not provided in MMC's 3D model report such as increasing buffer zones or using multiple plugs in the adits during closure. Such mitigation would be evaluated after additional data were collected during the Evaluation Phase.

With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

Source: Geomatrix 2011a; East Fork Bull River results based on Geomatrix, pers. comm. 2011c.

Mitigation measures and monitoring requirements in Alternatives 3 and 4 are reasonable stipulations for protection of the wilderness character and are consistent with the use of the land for mineral development. Alternatives 3 and 4 would be conducted to protect the surface resources in accordance with the general purpose of maintaining the wilderness unimpaired for future use and enjoyment as wilderness and to preserve the wilderness character consistent with the use of the land for mineral development and production in compliance with 36 CFR 228.15 and the Wilderness Act. The agencies' mine and transmission line alternatives would comply with the Wilderness Act. Alternatives 3 and 4 would minimize adverse environmental impacts on surface resources within the wilderness, and thereby comply with the regulations (36 CFR 228, Subpart A) for locatable mineral operations on National Forest System lands.

36 CFR 228.8(h) states that "certification or other approval issued by state agencies or other federal agencies of compliance with laws and regulations relating to mining operations will be accepted as compliance with similar or parallel requirements of these regulations." DNRC's permit decision and associated conditions on beneficial water use permits would constitute compliance with Montana groundwater use requirements.

3.10.4.7 Irreversible and Irretrievable Commitments

Most of the total precipitation that falls in the Cabinet Mountains flows from the mountains as surface water and groundwater. The total water yield varies from year-to-year as a function of the total precipitation and varying amounts of evapotranspiration. Some water would be used consumptively by the project, reducing the total yield of the region by that amount. Relative to the total yield of the affected watersheds, the consumptively used volume would be small. The reduction in yield would be an irretrievable commitment of resources.

In addition to water consumptively used, the estimated increase in groundwater storage due to the mine void would be about 34,600 acre feet, assuming 120 million tons of ore and 3.2 million tons of waste rock were mined. With mitigation of increased buffers and barrier pillars, if necessary, the mine void and the increase in groundwater storage would be slightly smaller. This volume of groundwater required to fill the mine void would be an irretrievable commitment of resources.

After the mine void filled, the total water yield of the region would return to pre-mining conditions, but because of the large mine void, the distribution of water produced along the headwaters of the four major streams that drain the area would be permanently changed. Without mitigation, the large mine void with an infinitely high hydraulic conductivity would permanently change the groundwater flow paths from the East Fork Rock Creek watershed toward the East Fork Bull River watershed. Mitigation would be designed to minimize post-mining changes in East Fork Rock Creek and East Fork Bull River streamflow and water quality. Without mitigation, the change in groundwater flow paths would be an irreversible commitment of resources.

Because of the potential for permanent change in groundwater flow paths, there may be slight changes in the relative contribution of deeper and shallow groundwater to surface water bodies such as Rock Lake. Springs would be irreversibly covered by the tailings impoundment in all action alternatives.

3.10.4.8 Short-term Uses and Long-term Productivity

As described above, there would be a short-term reduction in available water from this portion of the Cabinet Mountains equal to the consumptive use of the mine. Given the overall flow rate of streams from this area, the total short-term change would be small. Long-term, water availability of this area would not be reduced, but the distribution among the four major drainages may be slightly altered.

3.10.4.9 Unavoidable Adverse Environmental Effects

The consumptive use of groundwater by the project would unavoidably reduce the total water yield from this portion of the Cabinet Mountains. The anticipated consumptive use would be small relative to the total water yield of this area. Water yield would remain reduced until the project no longer consumptively uses water, and then slowly return to the pre-mining yield as the mine void filled, which would require about a predicted 493 years and longer with the agencies' mitigation. Without mitigation, water levels over portions of the mine void would permanently remain greater than 100 feet below pre-mine conditions and between 500 and 1,000 feet in a small area north of Rock Lake. Without mitigation, water levels closest to Rock Lake (in mining block 18) are predicted to remain 45 feet below pre-mine conditions, and less with mitigation. Total yield would be the same after the mine void reached steady state conditions, when recharge equaled discharge.

3.11 Surface Water Hydrology

This section provides information on analysis area streams, springs and lakes, and potential consequences to streamflow, spring flows, and lake levels resulting from the mine and transmission line alternatives. Surface water quality is discussed in section 3.13, *Water Quality*.

3.11.1 Regulatory Framework

3.11.1.1 Federal Requirements

The Organic Administration Act authorizes the Forest Service to regulate the occupancy and use of National Forest System lands. The Forest Service's locatable minerals regulations are promulgated at 36 CFR 228, Subpart A. The regulations apply to operations conducted under the U.S. mining laws as they affect surface resources on National Forest System lands under the jurisdiction of the Secretary of Agriculture. One of the mineral regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources. 36 CFR 228.8 also requires that mining operators comply with applicable state and federal water quality standards including the Clean Water Act; take all practicable measures to maintain and protect fisheries and wildlife habitat which may be affected by the operations; and reclaim the surface disturbed in operations by taking such measures as preventing or controlling onsite and off-site damage to the environment and forest surface resources. All waters within the boundaries of National Forests may be used for domestic, mining, or irrigation purposes, under applicable state laws. 36 CFR 228.8(h) states that "certification or other approval issued by state agencies or other federal agencies of compliance with laws and regulations relating to mining operations will be accepted as compliance with similar or parallel requirements of these regulations."

The Wilderness Act allows mineral exploration and development under the General Mining Law to occur in wilderness to the same extent as before the Wilderness Act until December 31, 1983, when the Wilderness Act withdrew the CMW from mineral entry, subject to valid and existing rights. 36 CFR 228.15 provides direction for operations within the National Forest Wilderness. Holders of validly existing mining claims within the National Forest Wilderness are accorded the rights provided by the U.S. mining laws and must comply with the Forest Service Locatable Minerals Regulations (36 CFR 228, Subpart A). Mineral operations in the National Forest Wilderness are to be conducted to protect the surface resources in accordance with the general purpose of maintaining the wilderness unimpaired for future use and enjoyment as wilderness and to preserve the wilderness character consistent with the use of the land for mineral development and production.

The Federal Water Pollution Control Act (Clean Water Act) is designed to protect and improve the quality of water resources and maintain their beneficial uses. Proposed mining activities on National Forest System lands are subject to compliance with Clean Water Act Sections 401, 402 and 404 as applicable. The DEQ, EPA, and the Corps all have regulatory, compliance and enforcement responsibilities under the Clean Water Act.

Executive Order 11988, Floodplain Management requires federal agencies to avoid to the extent possible the long and short-term adverse impacts associated with the occupancy and modification of floodplains and to avoid direct and indirect support of floodplain development wherever there is a practicable alternative. The order applies to impacts on 100-year floodplains designated by the Federal Emergency Management Agency (FEMA).

The KFP contains standards related to streamflow and floodplains. A floodplain/wetland analysis will be made for all management actions involving wetlands, streams, or bodies of water. Projects involving significant vegetation removal will require a watershed cumulative effects feasibility analysis to ensure that water yield or sediment will not increase beyond acceptable limits. Appendix 18 of the KFP contains guidelines concerning peak flow increases.

3.11.1.2 State Requirements

3.11.1.2.1 Nondegradation Rules

All of the waters in the analysis area are high quality waters. High quality waters are those waters whose quality is higher than the established standards (high quality state waters are defined in the Montana Water Quality Act (75-5-103(13), MCA)). The Montana Water Quality Act prohibits degradation of high quality waters unless the DEQ issues an authorization to degrade. The current nondegradation rules were adopted in 1994 in response to amendments to Montana's nondegradation statute in 1993 and apply to any activity that is a new or increased source that may degrade high quality water. These rules do not apply to water quality parameters for which an authorization to degrade was obtained prior to the 1993 amendments to the statute. NMC, MMC's predecessor, obtained an authorization to degrade in 1992 for certain water quality parameters. For those parameters, the limits contained in the authorization to degrade apply. For those parameters not covered by the authorization to degrade, such as flow, the applicable nonsignificance criteria established by the 1994 rules, and any subsequent amendments, apply (ARM 17.30.715), unless MMC obtained an authorization to degrade under the current statute.

The Montana Water Quality Act defines "degradation" as a change in water quality that lowers the quality of high-quality waters for a parameter, unless the change is nonsignificant. Current nondegradation rules provide that if an activity increases or decreases the mean monthly flow of a stream by less than 15 percent or the 7-day, 10-year ($7Q_{10}$) low flow of a stream by less than 10 percent such changes are not significant for purposes of the statute prohibiting degradation of state waters (ARM 17.30.715(1)(a)). Notwithstanding compliance with the nonsignificance criteria in ARM 17.30.715(1), the DEQ may determine under ARM 17.30.715(2) that a change in water quality is degradation based on the following criteria: a) cumulative impacts or synergistic effects; b) secondary byproducts of decomposition or chemical transformation; c) substantive information derived from public input; d) changes in flow; e) changes in the loading of parameters; f) new information regarding the effects of a parameter; or g) any other information deemed relevant by the DEQ and that relates to the criteria in ARM 17.30.715 (1). Under ARM 17.30.715(3), the DEQ may determine that a change in water quality is nonsignificant based on information submitted by an applicant that demonstrates conformance with the guidance found in 75-5-301(5)(c), MCA which is: i) potential for harm to human health, a beneficial use, or the environment; ii) strength and quantity of any pollutant; iii) length of time the degradation will occur; and iv) the character of the pollutant so that greater significance is associated with carcinogens and toxins that bioaccumulate or biomagnify and lesser significance is associated with substances that are less harmful or less persistent. Such a determination would be submitted for public comment before making a decision. Under the Montana Water Quality Act, no authorization to degrade may be obtained for outstanding resource waters, such as surface waters within a wilderness.

3.11.1.2.2 Other State Requirements

Under the Montana Floodplain and Floodway Management Act, the DNRC regulates flood-prone lands and waters to prevent and alleviate flooding threats to life and health and reduce private and public economic losses. The following uses are prohibited within floodways and floodplains, unless a variance is obtained:

- A structure or excavation that would cause water to be diverted from the established floodway, cause erosion, obstruct the natural flow of water, or reduce the carrying capacity of the floodway
- The construction or permanent storage of objects subject to flotation or movement during flood events (76-5-403, MCA)

Some mine facilities would be located in a floodplain, based on conceptual designs presented in Chapter 2. Transmission line facilities are not subject to the Montana Floodplain and Floodway Management Act. If at final design mine facilities would be in a floodplain, a variance application would be submitted to the DNRC that provides details on the obstruction or use of a floodway/ floodplain and a permit would be required before construction. DNRC's permit issuance is based on the danger to life and property downstream, availability of alternate locations, possible mitigation to reduce the danger, and the permanence of the obstruction or use (76-5-405, MCA).

The MFSA directs the DEQ to approve a facility if, in conjunction with other findings, the DEQ finds and determines that the facility would minimize adverse environmental impacts considering the state of available technology and the nature and economics of the various alternatives. A floodplain permit would not be needed for the transmission line if a MFSA certificate was issued.

The Montana Natural Streambed and Land Preservation Act requires a 310 Permit for any activity that physically alters or modifies the bed or bank of a perennially flowing stream (see section 1.6.2.4, *Montana Department of Natural Resources and Conservation* in Chapter 1). The permit application must be submitted to the local Conservation District. The project must be designed and constructed to minimize adverse impacts on the stream, minimize erosion, retain the original stream length or otherwise provide hydrologic stability, protect streambank vegetation, and minimize impacts on aquatic life.

3.11.2 Analysis Area and Methods

3.11.2.1 Analysis Area

The analysis area for surface water hydrology, water rights, and water quality includes all areas where surface water may be measurably affected either by the construction, operations or closure of the mine the transmission line or Sedlak Park Substation and loop line. The analysis area consists of four major watersheds and their tributaries: Libby Creek and its tributaries Howard Creek, Ramsey Creek, Poorman Creek, Midas Creek, Little Cherry Creek, Bear Creek and its tributary Cable Creek, Big Cherry Creek, and Swamp Creek; the Fisher River and its tributaries Sedlak Creek, West Fisher Creek and its tributary Standard Creek, Miller Creek, and Hunter Creek; Rock Creek and its tributary East Fork Rock Creek; and East Fork Bull River and its tributaries Placer Creek and Isabella Creek (Figure 76). Three other streams, Flower Creek, Copper Gulch, and West Fork Rock Creek, are briefly described in the Affected Environment section because they may be used for bull trout mitigation. Streams located outside the analysis area, such as the Bull River, may be affected by the project, but effects would be negligible.

Swamp Creek and Wanless Lake, both on the west side of the Cabinet Mountains, would not be affected by the project and would serve as benchmark monitoring locations. Lakes in the analysis area include Howard Lake, Ramsey Lake, Rock Lake, St. Paul Lake, Isabella Lake, and Libby Lakes; some of these lakes are not expected to be affected by the project. Other lakes in the CMW, such as Cliff and Copper lakes, are outside the analysis area because the 3D model did not predict they would be affected by the project.

3.11.2.2 Baseline Data Collection

Surface water investigations included a review of previous permits and authorizations, existing water use, an analysis of the watersheds potentially impacted by the project, floodplain mapping, streamflow, spring flow, peak streamflow calculations, lake levels and surface water quality sampling. Water resource baseline investigations were initiated in the analysis area by U.S. Borax in 1986 and 1987, continued by NMC in 1988 through 1994 and by MMC in 2004, 2005, and 2007 to 2013. In addition, the DEQ collected water resources information in the CMW in 1998 to 2000, followed by additional surface water data collection in the CMW by MMC in 2005. Streamflow measurements were collected in the analysis area by the KNF between 1960 and 2010. Additional streamflow measurements also were collected by NMC and MMC from 1998 through 1995 and 2001 through 2013 and by the DEQ in 1998 to 2000. Streamflow monitoring stations are shown on Figure 76. KNF gaged streamflow sites are on Libby Creek at US 2, West Fisher Creek, Miller Creek, lower East Fork Bull River, and lower Rock Creek. Four gaged sites also are on the Fisher River. MMC began continuously measuring the flow of upper Libby Creek in the summer of 2009. MMC also began continuously measuring the level of Rock Lake in the summer of 2009. Gurrieri (2001) and Gurrieri and Furniss (2004) measured and reported lake stage, surface inflows and outflows, and precipitation at Rock Lake in 1999 to complete a lake water balance. Available data collected by these various entities through 2013 are included in the EIS analysis.

3.11.2.3 Impact Analysis Methods

3.11.2.3.1 Streamflow

Streamflow changes may occur due to mine and adit dewatering, pumpback well system operation around the impoundment, evaporative losses from a tailings impoundment or LAD Areas (in Alternative 2), water appropriations from the Libby Creek watershed during high flows, discharges from a Water Treatment Plant or to the LAD Areas (the latter in in Alternative 2), vegetation clearing, and potable water use. To determine changes in streamflow and lake levels that may occur during the five mine phases, the capture, use, and discharges of water within each affected watershed for each mine alternative were evaluated. In addition, because the mine would intercept groundwater that may be a source of water to springs, lakes, and streams, the effects on surface water from underground mining also were evaluated.

A 2D numerical model of the mine area was developed to assess mine inflow and changes to baseflow (ERO Resources Corp. 2009). The primary objective of using a 2D model was to establish a hydrogeologic framework that could be used to evaluate potential mine impacts and develop possible impact mitigation. The baseflow of the mine area streams was modeled, as was the interaction of stream baseflow with the groundwater system. The agencies used the 2D model results for the basis of the hydrology effects analysis in the Draft EIS. Subsequently, MMC prepared a more complex 3D model of the analysis area (Geomatrix 2011a). The 3D model used the facility configuration in Alternative 3 in the analysis. Although the results of the two models are similar, the 3D model better represents the anticipated effects on streamflow and the 3D model results are used for the effects analysis. Similarly, the results of a 3D model of a pumpback well system at the Poorman Impoundment Site were used to assess effects of groundwater pumping on streamflow (Geomatrix 2010c). The effects on streamflow of Alternatives 2 and 4 have not been quantified and would be similar to effects described for Alternative 3 for east side streams and the same as Alternative 3 for west side streams. The effects of Alternatives 2 and 4 are discussed qualitatively and the effects of Alternative 3 are discussed quantitatively.

Sensitivity analyses were performed for each of the groundwater models and the results provided in ERO (2009) and Geomatrix (2011a). In addition, each model report discusses overall uncertainty of the respective model results. There is uncertainty associated with the hydraulic properties of the bedrock and faults; predictions of mine inflows and impacts on water resources are sensitive to permeability of major fault zones. With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both groundwater flow models would be refined and rerun after data collected during the Evaluation Phase were incorporated into the models (see section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease.

Streamflow effects are described for four different flow periods: estimated $7Q_{10}$ flow, or in the case of higher elevation sites, baseflow, estimated $7Q_2$ flow, average flow, and peak flow. As discussed in section 3.8.3, 7-day, 10-year ($7Q_{10}$) low flow and 7-day, 2-year ($7Q_2$) low flow were derived for specific stream locations and the estimated $7Q_{10}$ and $7Q_2$ flow used to analyze the effects of mine activities on streamflow. The $7Q_{10}$ and $7Q_2$ low flows were estimated using a USGS method developed for ungaged watersheds (Hortness 2006). The equations used to estimate the $7Q_{10}$ and $7Q_2$ low flows used drainage area and mean annual precipitation as the location-specific variables (Hortness 2006). The estimated range of the $7Q_2$ and $7Q_{10}$ flows for analysis area streams is provided in Table 86 in section 3.8.3. With the exception of EFRC-200, LB-100, and LB-300, the estimated $7Q_{10}$ flow for the stream locations used in the streamflow analysis is lower than modeled baseflows. At EFRC-200, LB-100, and LB-300, where the estimated $7Q_{10}$ flow is greater than the modeled baseflow, the agencies used the lower modeled baseflow instead of the estimated$7Q_{10}$ flow to analyze effects. The use of estimated $7Q_2$ and $7Q_{10}$ flow (and modeled baseflow in lieu of $7Q_{10}$ flow at EFRC-200 and LB-300) provides an analysis of project effects when such effects would be most measurable.

The agencies used eight different locations to summarize streamflow effects from mine activities (Table 108 through Table 113); these locations are shown on Figure 76. The East Fork Rock Creek site, EFRC-200, is at the outlet of Rock Lake at the CMW boundary. The Rock Creek site, RC-2000, is at the mouth of Rock Creek above the confluence of the Clark Fork River. The East Fork Bull River site, EFBR-500, is at the CMW boundary. The sites on Little Cherry, Poorman, and Ramsey creeks are near the confluences of these creeks with Libby Creek. Two sites are on Libby Creek: LB-300 below the Libby Adit Site, and LB-2000 just above the confluence with Bear Creek. The effect on baseflow at LB-100 near the CMW boundary due to mine inflows was also evaluated.

these locations (Figure 76). One site is on Libby Creek (LB-2), located about 1 mile upstream of Little Cherry Creek, where the pumpback wells would reduce streamflow. Another site on the East Fork Rock Creek (RC-3) is about 1 mile upstream of the confluence with the West Fork Rock Creek, and the third site on the East Fork Bull River (EFBR-2) is at the confluence with Isabella Creek in the CMW. Effects due to mine inflows were predicted using the 3D groundwater model. In August through October 2012, KNF hydrologists collected stream cross-section measurements and measured stream velocity during various flow regimes at LB-2, RC-3, and EFBR-2. These data were used to calculate stream discharge at these locations and develop a relationship during low flows between the wetted cross section area (a total of 25 or more width and water depth measurements taken across a stream cross section, each multiplied and then added to derive total wetted perimeter at the cross section) and discharge. The wetted perimeter-discharge relationship for each site was used to estimate changes in the wetted cross-sectional area of the stream at these locations due to the project (ERO Resources Corp. 2012a). Additional data collection at RC-3 and EFBR-2 during low flows (proposed in the Appendix C Water Resources Monitoring Plan) would provide a more precise estimate of the relationship between discharge and wetted perimeter.

For all alternatives, construction of the tailings impoundment would alter the size of the watershed and the direction of runoff within the existing watersheds. Some of the runoff would be redirected by the configuration of the tailings impoundment to a watershed different from that of pre-mining conditions. To assess the effects of streamflow changes resulting from these changed watershed boundaries, the agencies analyzed the changes in watershed areas as an indicator of possible streamflow changes (ERO Resources Corp. 2010a in Appendix H). NewFields (2014b) completed a similar analysis for the watersheds in which the Poorman Impoundment would be constructed. NewFields analysis used for detailed LIDAR topographic mapping to assess changes in the Poorman Impoundment Site watersheds, and consequently the watershed sizes vary slightly. The differences between the two analyses were negligible. The agencies assumed that watershed area is directly related to streamflow in the receiving stream of each watershed. Use of watershed or drainage area is consistent with the Hortness (2006) method of estimating $7Q_2$ and $7Q_{10}$ flows at ungaged, unregulated streams. The agencies also assumed any differences in runoff due to elevation, soil type, vegetation cover, slope, and aspect are negligible across the analysis area. Within the small watersheds of the tailings impoundment sites (2.6 square miles in Alternatives 2 and 4, and 1.2 square miles in Alternative 3), these differences are likely small. The existing footprints for the tailings impoundments and associated facilities were plotted over the watershed boundaries. Changes to all watersheds were either added or subtracted from the existing watershed area, depending on whether the change would increase or decrease watershed area, and therefore water, to the watershed. Calculations were completed for the three alternatives for Operations and Post-Closure Phases. The watershed analysis is presented in Appendix H and summarized in the Environmental Consequences section for each alternative.

The KFP contains water yield guidelines based on instream resource values (Appendix 18, KFP, USDA Forest Service 1987a). Forest clearing for roads or other activities can alter normal streamflow dynamics, particularly the volume of peak flow and baseflow. The degree to which streamflow changes depends on the road density, percentage of total tree cover removed from the watershed, and the amount of soil disturbance caused by the harvest, among other things. For example, if harvest activities remove a high percentage of tree cover and cause light soil disturbance and compaction, rain falling on the soil would infiltrate normally. Due to the loss of tree cover, evapotranspiration (the loss of water by plants to the atmosphere) would be lower than before. The combination of normal water infiltration into the soil and decreased uptake of water by tree cover results in higher streamflow. In general, timber clearing on a watershed scale results in water moving more quickly through the watershed because of decreased soil infiltration and evapotranspiration. Water yield estimates for the analysis area were determined using the KNF Equivalent Clearcut Acres Calculator (ECAC) (KNF 2012a). The ECAC model was designed as a tool to estimate the potential effects of ground disturbing activities such as road, transmission line, and other land clearing disturbances. The ECAC model results are provided in Appendix H. The effects of project discharges and the pumpback wells on peak flow would be very small (less than 1 percent of peak flow) and are not discussed further.

The removal of vegetation on a landscape has been shown to also increase annual water yields. Annual water yield predictions for the Montanore Project were based on both water yield modeling programs (ECAC and WATSED) used by the KNF. The ECAC model is a peak-flow centric model used by the KNF to evaluate potential impacts from land management. The ECAC model is based entirely on the outputs from relationships developed from the R1-WATSED model. Numerous WATSED model outputs have shown that based on similar watershed characteristics, annual water yield increases can be estimated from the predicted peak flow increase. The agencies completed an annual water yield analysis for all project alternatives (Appendix H). WATSED was not designed, nor is it used to develop exact estimates of flow. The utility of the model is that it provides a consistent method for comparing alternatives. The values generated by the model are used, in concert with other water resource information, to interpret the potential effects on a stream channel as a result of implementing a proposed land management activity. Effects are analyzed with regard to normal or average conditions. Episodic climatic events such as rain-on-snow, high intensity thunderstorms, mass soil movement, or short-duration peak flows cannot be addressed in the model. Analysis of these types of events, where needed, must be completed using professional judgment or other models (USDA Forest Service 2011d).

3.11.2.3.2 Lake Levels and Volume

Potential changes in Rock Lake volume, level, and surface area without and with MMC's modeled mitigation (partial grouting in the mine near Rock Lake and installing two bulkheads post-mining) were quantitatively estimated using the 3D model results (ERO Resources Corp. 2012b). Gurrieri (2001) developed an estimate of the volume of Rock Lake and a relationship of volume to lake level and surface area. Uncertainties in the volume/stage/surface area relationships result from the low number of soundings collected at the lake, the inexact method of locating the soundings on the map, and the fact that few, if any, soundings were collected in the shallow areas of the lake near the shoreline (where the predicted effects on Rock Lake discussed in section 3.11.4 would occur). The 3D model predicted that as a result of a decline in the potentiometric surface due to mine inflows, the supply of bedrock groundwater to Rock Lake would decrease during all phases of mining (Geomatrix 2011a). The effects on Rock Lake during the mine phases and post-mining were quantified for a 2-month late summer/early fall period when the only source of supply to Rock Lake is assumed to be deep bedrock groundwater. The effect on the lake was also quantified for a 7-month winter period when Rock Lake is frozen and the only source of supply is assumed to be deep bedrock groundwater.

To be able to quantify the effects during the 2-month late summer/early fall period, the agencies assumed that without the effect of the mine, the lake is in equilibrium (lake inflow=lake outflow), no runoff from precipitation or snowmelt occurs during the 2-month period, and the lake is full at the start of the period. The reductions in groundwater flow to Rock Lake provided for each mine phase and after mine closure in the 3D model were used to estimate the change in lake volume and corresponding change in lake level for the 2-month period.

For the 7-month winter period, to quantify the effect of the mine post-closure, the agencies assumed the lake is in equilibrium (lake inflow=lake outflow), the lake is frozen for the entire period and no water evaporates from the lake, and water flows out of the lake downstream in a rate equal to groundwater flow into the lake. Due to late fall precipitation, Rock Lake was assumed to be full at the beginning of the 7-month winter period. The only change expected to occur during the 7-month winter period would be a change in water stored in Rock Lake when the potentiometric surface would be lower than the surface of the lake.

The analysis of effects on Rock Lake is based on the conceptual model of the groundwater flow systems used in both the 2D and 3D numerical models. Based on the conceptual model and the results of the 3D model, the agencies developed a water balance for Rock Lake that included groundwater inflow to the lake, evaporation, and surface inflow and outflow. A previous investigation (Gurrieri 2001) of Rock Lake used a different approach to develop a water balance for the lake. Using measured surface water inflow and outflow and water chemistry, Gurrieri developed a water balance that had an estimated groundwater outflow component. Using this water balance, Gurrieri analyzed the effects to Rock Lake of mine dewatering. The effects of the Gurrieri analysis were slightly greater, but within the range of model-predicted effects (Table 114 and Table 115).

Based on the following information, other lakes in the analysis area were dismissed from detailed analysis. St. Paul Lake is located within glacial moraine material, which causes the lake level to fluctuate to a much greater extent than does Rock Lake. Another difference between the two lakes is that the watershed above St. Paul Lake is north facing (Rock Lake's is south facing), and the snowpack above St. Paul Lake melts more slowly. St. Paul Lake may be affected by mining, but effects may be difficult to separate from the large, natural lake level variations. If deep groundwater was a component of the inflow to St. Paul Lake, mine dewatering would unavoidably reduce this source of water to the lake, and the lake level may lower more quickly during dry years when the only source of water to the lake was bedrock groundwater. Because the Libby Lakes and Isabella Lake are at an elevation of about 7,000 feet, and perched above the regional potentiometric surface, they likely would not be affected by mining dewatering. The KNF began monitoring the level of Lower Libby Lake in 2010; the recorder housing failed in 2013 and it was replaced in 2014. MMC would continue monitoring the water level of Lower Libby Lake (see Appendix C). Howard Lake is at an elevation of 4,100 feet southeast of the Libby Adit, and would be too far from mine dewatering to be affected. Ramsey Lake, near the proposed Ramsey Plant Site and the Ramsey Adits proposed in Alternative 2, is at an elevation of about 4,450 feet. Ramsey Lake is fed mostly by snowmelt and water flowing in shallow surface deposits in the Ramsey Creek drainage (Wegner, pers. comm. 2008). In September 2012, no flow was observed into the lake and an estimated 1 to 2 gpm was flowing out of the lake (NewFields 2013a). The Ramsey Lake level varies substantially and changes in the lake level due to mine inflows probably would not be detectable. Effects on Isabella Lake, St. Paul Lake, the Libby Lakes, Howard Lake, and Ramsey Lake are not discussed further. Effects on springs are discussed in section 3.10.4, *Groundwater Hydrology*.

3.11.2.3.3 Floodplains and Stream Crossings

To determine if mine or transmission line facilities would be located within 100-year floodplains designated by the FEMA, a GIS analysis was completed by overlaying the proposed facilities over the FEMA floodplain data for Sanders and Lincoln counties. GIS analysis for the transmission line alternatives included comparing the stream and floodplain crossings required for the mine and transmission line alternatives, providing the watershed acreage for Class 1 and 2 streams where roads would be built or trees cleared for other purposes, and determining the acreages of disturbance for impaired streams. The Alternative 2 and 4 tailings impoundments would be located with the floodplain of Little Cherry Creek, which has not been designated as a 100-year floodplain by FEMA. Kline Environmental Research (2005a) provided the approximate area of floodplain that would be affected by the Little Cherry Creek tailings impoundment in Alternatives 2 and 4.

3.11.3 Affected Environment

3.11.3.1 Relationship of Surface Water and Groundwater

Lakes and streams that exist above an elevation ranging between 5,000 and 5,600 feet within the analysis area are likely not connected hydraulically to deeper bedrock groundwater, but rather are supplied by surface runoff, snowmelt and/or drainage from unconsolidated, discontinuous surface deposits that store precipitation and snowmelt water. Streams located below the range of 5,000 to 5,600 feet generally are perennial, supplied by surface runoff, shallow groundwater, and groundwater from deeper bedrock fractures that intersect the ground surface. Some sections of these streams flow intermittently during some parts of the year due to the loss of surface flows into the underlying alluvium. At both tailings impoundment sites, the plant sites and the LAD Areas, groundwater occurs in unconsolidated glaciofluvial and glaciolacustrine deposits. The deposits range in thickness from 0 feet at bedrock outcroppings near the Little Cherry Creek impoundment site to more than 200 feet thick at the Poorman Impoundment Site. Groundwater discharges from these deposits to springs, alluvium, and Libby, Poorman and Ramsey creeks. Section 3.10.3*, Affected Environment* of the *Groundwater Hydrology* section discusses the relationship of groundwater, springs and streams in the analysis area. Chart 16 and Chart 17 portray conceptually the relationship of the various components of streamflow in watersheds in the analysis area.

3.11.3.2 Watersheds, Floodplains and Water Sources

Underground mining would occur beneath a divide separating three drainages: East Fork Rock Creek, East Fork Bull River, and Libby Creek. Except for a small ventilation adit near Rock Lake, proposed surface mine facilities in all mine alternatives would be located in the Libby Creek drainage. The mine area is drained on the east by Libby Creek and its tributaries: Ramsey, Poorman, Little Cherry, and Bear creeks (Figure 76). Libby Creek flows north from the analysis area to its confluence with the Kootenai River near Libby. The East Fork Rock Creek flows southwest, joining West Fork Rock Creek to form Rock Creek, which flows into the Clark Fork River downstream of Noxon Reservoir. The East Fork Bull River flows northwest into the Bull River. Several alpine lakes occur in the analysis area (Figure 76). Many of these lakes are located in glacial cirques that act as collection basins for runoff and snowmelt.

Chart 16. Typical Relationship of Various Components of Annual Streamflow in Analysis Area Watersheds.

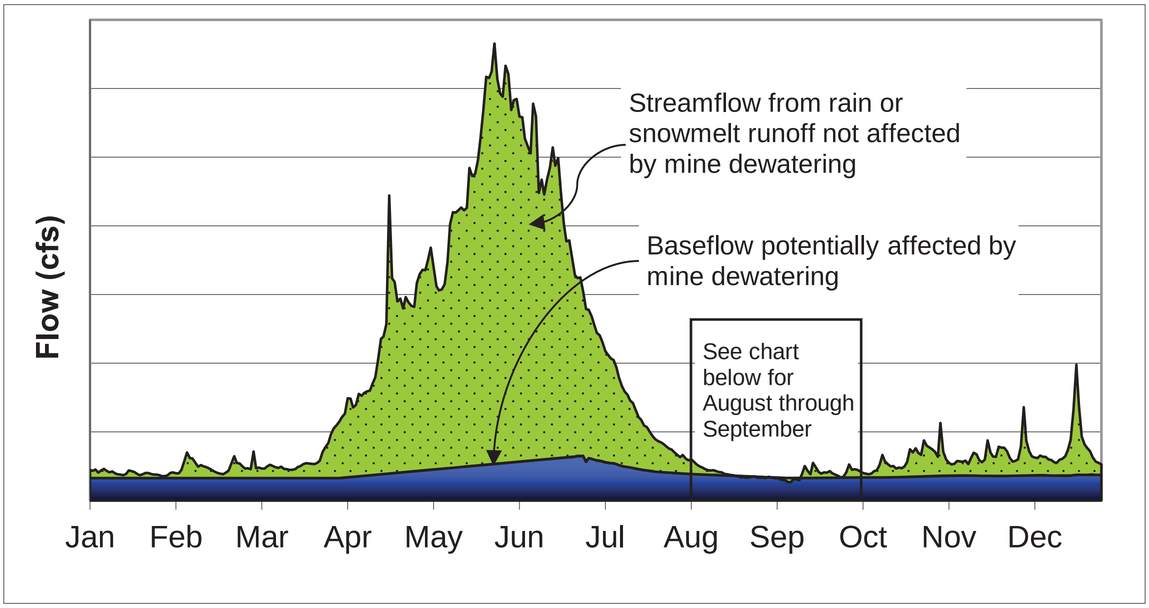

Chart 17. Typical Relationship of Various Components of Streamflow during $7Q_{10}$ Flow in Analysis Area Watersheds.

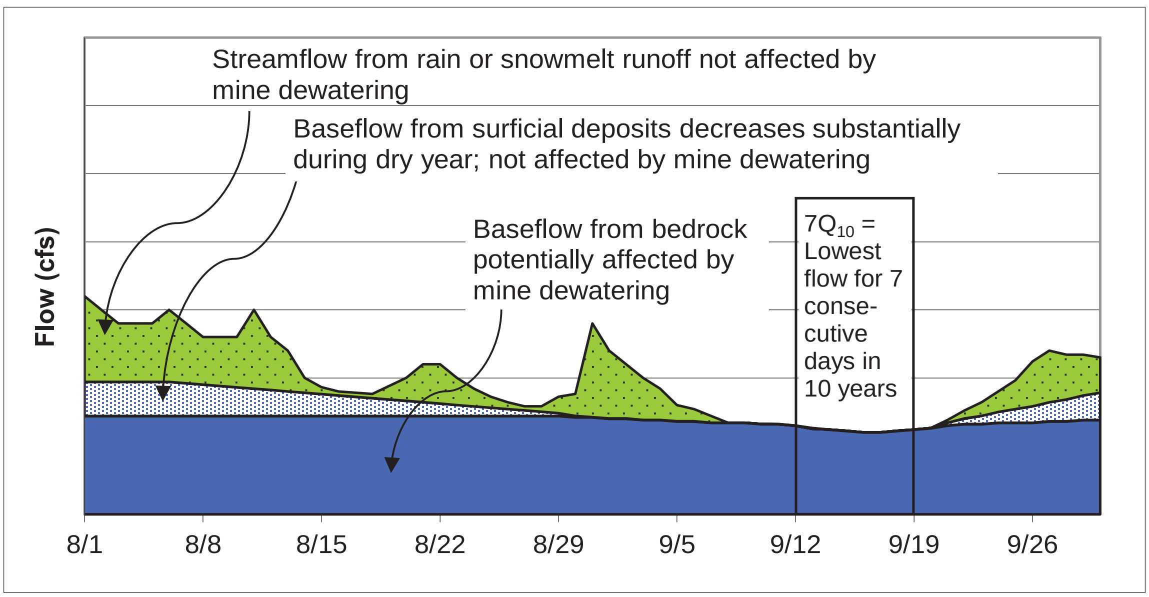


The transmission line corridor area is drained by the Fisher River and its tributaries: Sedlak Creek, Hunter Creek, Standard Creek, West Fisher Creek, and Miller and North Fork Miller creeks; and by Libby Creek and its tributaries: Howard Creek, Midas Creek, and Ramsey Creek, all perennial streams. Numerous unnamed ephemeral streams also drain the analysis area (Figure 76). One hundred-year floodplains have been designated along the Fisher River, Miller Creek, an unnamed tributary to Miller Creek, Ramsey Creek, and Libby Creek (Power Engineers, Inc. 2006a).

Snowmelt, rainfall, and groundwater discharge are the main sources of supply to streams, lakes, and ponds in the analysis area. Precipitation ranges from 100 inches per year at higher elevations in the Cabinet Mountains to about 30 inches per year at the tailings impoundment site. The highest precipitation occurs in November through February and the lowest in July through October.

Baseflow is the contribution of near-channel alluvial groundwater and deeper bedrock groundwater to a stream channel. Baseflow does not include any direct runoff from rainfall or snowmelt into the stream. Because the near surface geology varies between the upper and lower reaches of streams in the analysis area, the source of groundwater to streams also varies. The sources in the analysis area are unconsolidated deposits (alluvium and colluvium), weathered bedrock, and fractured bedrock. In some of the upper stream reaches, little if any alluvium, colluvium, or weathered bedrock are present. Other reaches, such as in the upper Libby and Ramsey creek drainages, contain surficial deposits within avalanche chutes that may store and transmit shallow groundwater through much of the summer depending on remaining snow pack at the head of each chute. Flow rates measured during late summer/early fall in upper Libby Creek are similar to the 3D model predicted baseflows, indicating that there may be little if any contribution from surficial deposits during late summer/early fall during years with little or no late season snow pack or precipitation. The primary source of baseflow to streams in the upper reaches is fractured bedrock up to an elevation in the analysis area of between 5,000 and 5,600 feet. Drainages above an elevation of about 5,000 to 5,600 feet are above the regional potentiometric surface and receive water from surface water runoff and from limited perched shallow groundwater in unconsolidated deposits such as talus. The shallow groundwater is from precipitation and drains quickly. The smallest, highest first order streams are ephemeral, while the second order channels (such as upper Libby Creek) into which the first order streams flow are generally intermittent. Second order channels become perennial when they intersect the regional potentiometric surface below between 5,000 and 5,600 feet. In general, the thickness of the unconsolidated surficial deposits increases in a downstream direction, and the deposits can store more groundwater where they are thicker. The fractured bedrock is hydraulically connected to the weathered bedrock and surficial deposits, so it is difficult to separate the individual sources of groundwater flow to streams in the middle and lower reaches of the drainages. Baseflow in the lower reaches is likely dominated by groundwater flow from the thicker surficial deposits. During the year, there is probably an ever-changing ratio between shallow groundwater (from the surficial deposits and weathered bedrock) and deeper bedrock groundwater contributions to any one stream. Streams in the analysis area do not reach baseflow every year.

Few streamflow data from the upper reaches of most analysis area streams draining the CMW are available. It is likely that during non-baseflow periods, streamflow is probably much greater than during the baseflow period, but actual flow rates are unknown. The agencies reviewed the hydrograph from three perennial stream locations (Granite Creek and Flower Creek, located near Libby, Montana, and Boulder Creek, near Leonia, Idaho) where between 22 and 50 years of continuously recorded annual flow data exist (ERO Resources Corp. 2009). Based on these three streams, which are analogous to streams in the lower reaches of the Montanore Project analysis area, it appears that perennial streams in the area with a baseflow component may flow at baseflow for about 1 to 2 months sometime between mid-July to early October. The stream hydrographs indicate that periods of baseflow also may occur during November through March.

3.11.3.2.1 Watershed Descriptions

Libby Creek and Libby Lakes

Libby Creek is the primary watershed within the analysis area. Libby Creek flows northward and joins the Kootenai River near the town of Libby. Libby Creek is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012). Within the analysis area, the primary tributaries to Libby Creek are Ramsey, Poorman, Little Cherry, and Bear creeks (Figure 76). The highest elevation of the Libby Creek watershed is 8,740 feet. Libby Creek originates in a steep, glacial-carved basin, and discharges to the Kootenai River 29 miles downstream at an elevation of 2,060 feet. Libby Creek drains an area of about 68 square miles upstream of where the stream crosses US 2. The first 0.5 mile of Libby Creek flows intermittently. The Libby Creek valley widens downstream, where more erodible alluvial, glaciolacustrine, and glaciofluvial deposits are encountered. Where Libby Creek is perennial, flow is sustained by groundwater discharge. The average slope of upper Libby Creek is 6.6 percent (up to 30 to 40 percent near the top), and the creek contains pools, glides, riffles, rapids and cascades (Kline Environmental Research and NewFields 2012). The creek is a third-order stream near the proposed mine facilities. It is primarily restricted to a narrow channel flowing through bedrock canyons, erodible valley fill material, and glaciolacustrine sediment. Unstable stream channel characteristics in the Libby Creek drainage can be attributed, in part, to historical placer mining by hand (late 1800s), hydraulic and dredge mining (early to mid-1900s), and logging/clearcutting (early to mid-1900s).

The Libby Lakes are small and lie within closed depressions along the crest of the Cabinet Mountains. Drainage from Upper Libby Lake is tributary to the East Fork Rock Creek above Rock Lake and Middle and Lower Libby Lakes are tributary to Libby Creek.

A FEMA-designated 100-year floodplain is mapped along Libby Creek, from 4,000 feet above the confluence with Howard Creek to US 2.

Ramsey Creek and Ramsey Lake

The highest elevation of the Ramsey Creek watershed is 7,940 feet. Ramsey Creek is 5.3 miles long, and discharges to Libby Creek at an elevation of 3,425 feet. Its entire length is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012). The total drainage area for Ramsey Creek is about 6.5 square miles. The upper part of the creek has two tributaries, one from the north and one from the south. The southern tributary originates at 5,598 feet, is 3,200 feet in length, and has a slope of 43 percent (Kline Environmental Research and NewFields 2012). The northern tributary is not in the GDE inventory area. The upper watershed is poorly drained and contains both a marshy area and Ramsey Lake, a small lake of about 2 acres (Figure 76). Water in the marsh flows through a series of ponds and meanders through grassy, wet meadows. Downstream of the meadows, Ramsey Creek is a high-energy stream flowing through a series of narrow bedrock canyons and glacial moraine material. Ramsey Creek is a perennial stream with heavily forested banks. The mainstem of Ramsey Creek is a second-order stream, is fairly flat and contains glides, pools and riffles (Kline Environmental Research and NewFields 2012).

A FEMA-designated 100-year floodplain is mapped along 4,000 feet of headwaters of Ramsey Creek near the CMW boundary.

Poorman Creek

The highest elevation of the Poorman Creek watershed is 7,655 feet. Poorman Creek is 5.3 miles long, and joins Libby Creek at an elevation of 3,320 feet. Its entire length is rated as outstanding

(Class 1) for fisheries habitat by the FWP (FWP 2012). The drainage area is about 6 square miles. Poorman Creek is a small, perennial stream located south of the Poorman Tailings Impoundment Site and north of the LAD Areas. Near the proposed mine facilities, Poorman Creek is a second-order stream. In the uppermost reach, which originates at 5,574 feet, the creek is steep (gradient typically between 25 and 40 percent), and cascades over bedrock. When the gradient decreases, there are glides and pools in the creek. The creek flows in a narrow, straight channel with several small intermittent tributaries, heavily forested banks, and a boulder, cobble, and gravel bed. Streamflow is relatively constant both upstream and downstream (Kline Environmental Research and NewFields 2012).

Little Cherry Creek

The highest elevation of the Little Cherry Creek watershed is 7,040 feet. Little Cherry Creek is a perennial stream that drains about 1.9 square miles, and flows 3.1 miles to its confluence with Libby Creek at an altitude of 3,120 feet. Its entire length is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012). Streambed material ranges from boulders to sand and silt. Little Cherry Creek is incised into glaciolacustrine and glaciofluvial sediment, with a steep gradient reach where bedrock crops out in the lower section near its confluence with Libby Creek. The most complete synoptic flow data collected in Little Cherry Creek (Table 105) indicate that the creek gains water from groundwater discharges throughout its length (Geomatrix 2008b). Little Cherry Creek is a second-order stream.

The upper portion of the watershed is forested and the lower portion has been logged. In logged areas, stream banks are collapsed, and small shrubs and forbs have become established. The average bankfull width of upper Little Cherry Creek is 8 feet and 14 feet in the lower creek. Bankfull width is the width of the stream when carrying the 1.5- to 2-year peak flow (Rosgen 1996). The floodplain is estimated to range from 0 to 33 feet wide in the lower mile of the creek, and 33 to more than 100 feet wide above that location (Kline Environmental Research 2005a). The floodplain identified by Kline Environmental Research is not a FEMA-designated 100-year floodplain.

Bear Creek

Bear Creek is the largest tributary of Libby Creek in the analysis area, draining a 15-square mile area. The highest elevation of the Bear Creek watershed is 7,200 feet. Originating in a glacial basin, Bear Creek flows perennially 8.2 miles, converging with Libby Creek at an elevation of 3,050 feet. Its entire length is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012). Bear Creek is incised into lake bed (glaciolacustrine) silt, although small areas of exposed bedrock occur in portions of the channel area. Most of the watershed is heavily forested. The streambed material is composed primarily of cobbles and gravels.

Cable Creek

Cable Creek is a tributary to Bear Creek, with headwaters in the CMW. The highest elevation of the Cable Creek watershed is 7,195 feet, and enters Bear Creek at 3,650 feet in elevation. The entire 4.2 miles of Cable Creek is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012). The agencies expect that streamflow in Cable Creek would not be affected by the mine or transmission line, and it is not discussed further in this section.

Big Cherry Creek

The highest elevation of the Big Cherry Creek watershed is 8,740 feet, and its lowest elevation is 2,150 feet where it enters Libby Creek. Big Cherry Creek originates in a 5-acre lake and flows 19.2 miles to Libby Creek about 2 miles upstream of the Kootenai River. The stream shifts and braids within a wide, unvegetated cobble floodplain. Its entire length is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012). The agencies expect that streamflow in Big Cherry Creek would not be affected by the mine or transmission line, and it is not discussed further in this section.

Howard Creek and Howard Lake

Howard Creek is a tributary to Libby Creek. The highest elevation of the Howard Creek watershed is 6,870 feet and enters Libby Creek at 3,570 feet in elevation. Howard Lake is located near the headwaters of Howard Creek at an elevation of 4,100 feet and is 33 acres in size. The lake is adjacent to a KNF campground. All of the transmission line alternatives would cross lower Howard Creek and two of the transmission line alternatives would cross upper Howard Creek at its headwaters. The drainage area is about 2.3 square miles, and the watershed begins at about 5,380 feet. The creek is about 2.8 miles long. The entire length of Howard Creek is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012).

Midas Creek

The highest elevation of the Midas Creek watershed is 5,600 feet. Midas Creek is a tributary to Libby Creek that flows from the southeast into Libby Creek at an elevation of 3,290 feet a short distance downstream of Poorman Creek. The North Miller and Modified North Miller transmission line alternatives would cross into the upper Midas Creek watershed. The drainage area is about 6 square miles, and the watershed begins at about 5,750 feet. The creek is about 3.3 miles long. The entire length of Midas Creek is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012).

Swamp Creek

The highest elevation of the Swamp Creek watershed is 5,850 feet. It flows 10.4 miles to its confluence with Libby Creek near US 2 at an elevation of 2,720 feet. In Alternatives 3 and 4, MMC would acquire a 67-acre parcel along US 2 through which Swamp Creek flows for wetland mitigation. The agencies expect that the streamflow and water quality in Swamp Creek would not be affected by the mine or transmission line. Swamp Creek is not rated by the FWP for fisheries habitat (FWP 2012).

Fisher River

The Fisher River is a tributary to the Kootenai River. The river is formed by two tributaries, Silver Butte Fisher River and Pleasant Valley Fisher River. Miller Creek and West Fisher Creek flow into the river 3 to 4 miles below the confluence of the two tributaries. The river is 63 miles long and has a watershed area of 838 square miles. The highest elevation of the watershed is 7,565 feet and joins the Kootenai River at 2,115 feet in elevation just downstream from Libby Dam. In the analysis area, the river is rated as substantial (Class 3) for fisheries habitat (FWP 2012). A FEMA-designated 100-year floodplain is mapped along all segments of the Fisher River in the analysis area.

Miller Creek

Miller Creek is a tributary to the Fisher River located southeast of the mine area. Segments of three transmission line alignment alternatives are in the Miller Creek watershed. The drainage area is about 12 square miles; the highest elevation of the watershed is 5,595 feet and it joins the Fisher River at 2,885 feet in elevation. Its entire 6.2-mile length is rated as moderate (Class 4) for fisheries habitat by the FWP (FWP 2012). Sections of Miller Creek in the lower reaches near the confluence with the Fisher River are dry most of the year where water in the channel sinks below the channel bottom. The stream connects with the Fisher River only during spring high flows, or during rain-on-snow events. The transmission line alignment in Alternatives B and C-R would parallel an unnamed tributary to Miller Creek that flows from the north into Miller Creek. The drainage area of this tributary is 1.9 square miles, the top of the watershed begins at about 5,400 feet, and the length of the tributary is about 2.4 miles. A FEMA-designated 100-year floodplain is mapped along Miller Creek and its unnamed tributary, from 2,000 feet above the confluence of the two drainages to Miller Creek's confluence with the Fisher River.

West Fisher Creek

West Fisher Creek is also southeast of the mine area and is a tributary to the Fisher River. The West Fisher Creek transmission line alignment generally parallels the creek for about 5 miles. It has a large drainage area (44 square miles); the highest elevation of the watershed is 7,610 feet (in the CMW) and the lowest elevation is 2,900 feet where it joins the Fisher River. The creek has several lakes in its headwaters and numerous tributaries. Its entire 13.3-mile length is rated as moderate (Class 4) for fisheries habitat by the FWP (FWP 2012). A FEMA-designated 100-year floodplain is mapped along West Fisher Creek, from 2,000 feet above the confluence with Lake Creek to its confluence with the Fisher River. All transmission line alternatives except Alternative B would cross the creek.

Hunter Creek

Hunter Creek, a tributary of the Fisher River, has a small drainage area (1.64 square miles) that originates east of US 2. The highest elevation of the watershed is 5,345 feet with its lowest elevation at 2,910 feet where it joins the Fisher River. Alternative B is the only transmission line alternative that would cross the creek. Most of the watershed is on Plum Creek lands. Hunter Creek's 2-mile length is rated as moderate (Class 4) for fisheries habitat by the FWP (FWP 2012).

Sedlak Creek

The Sedlak Creek watershed is immediately south of Hunter Creek. Sedlak Creek flows into the Pleasant Valley Fisher River about 1,000 feet east of the proposed Sedlak Park Substation Site. Sedlak Creek has a small drainage area (1.04 square miles); the highest elevation of the watershed is 4,440 feet and its lowest elevation is 2,995 feet where it joins the Pleasant Valley Fisher River. Most of the watershed is on Plum Creek lands. Sedlak Creek's 2-mile length is rated as moderate (Class 4) for fisheries habitat by the FWP (FWP 2012).

Standard Creek

Standard Creek, a tributary to West Fisher Creek, drains a portion of the transmission line corridor area and would not be affected by the mine or by construction and maintenance of the transmission line. The highest elevation of the watershed is 6,870 feet and its lowest elevation is 3,450 feet where it joins West Fisher Creek. Short segments of the Miller Creek and West Fisher Creek transmission line alternatives would be within the Standard Creek watershed, but the line and any associated access roads would be located more than 1 mile from the creek. The agencies expect that streamflow and water quality in Standard Creek would not be affected, and it is not discussed further.

Rock Creek Watershed

Rock Creek is formed by the convergence of the east and west forks of the creek, which drain an area of about 33 square miles of steep, high-elevation terrain. In its uppermost ephemeral reaches, the source of water supply to the East Fork Rock Creek is surface water runoff, but where the stream becomes perennial, bedrock groundwater is also a source of water to the creek. The reach above Rock Lake is 0.4 mile in length, has a gradient between 10 and 20 percent, and cascades over boulders and bedrock. Below Rock Lake, the East Fork Rock Creek to the confluence with the West Fork Rock Creek is 5.3 miles long, has an average slope of 8 percent, and contains pools, glides, riffles, rapids and cascades (Kline Environmental Research and NewFields 2012).

Underground mining would occur under the headwaters of the East Fork Rock Creek. The highest elevation of the East Fork Rock Creek watershed is 7,610 feet and its lowest elevation is 2,770 feet where it joins the West Fork of Rock Creek to create the mainstem of Rock Creek. The East Fork Rock Creek and Rock Creek are rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012). The East Fork Rock Creek flows perennially, but loses water near the confluence with the West Fork (USFWS 2007a).

Rock Creek Meadows is a 50-acre wetland outside the CMW where the topography flattens along the East Fork Rock Creek drainage. Several tributaries to the East Fork Rock Creek drain directly to Rock Creek Meadows; the drainage area of these tributaries is 2,970 acres. The drainage area of the East Fork Rock Creek upstream of the Meadows is 1,070 acres. The wetlands, when observed during an agency field review during a very dry period in September 2007, had a visibly high water table, and an inflow from the East Fork Rock Creek of about 2 cfs.

The West Fork Rock Creek flows 3.5 miles to the mainstem of Rock Creek. The substrate is dominated by gravel and rubble, with high amounts of fine sediment. The drainage is subject to high flow events and intermittent flow. West Fork Rock Creek may be used for bull trout mitigation. The agencies expect that the streamflow and water quality in West Fork Rock Creek would not be affected by the mine or transmission line, and it is not discussed further in this section.

Rock Creek downstream of the confluence of the East and West forks has a gradient of about 2 percent, and contains pools, glides, riffles, and rapids (Kline Environmental Research and NewFields 2012). Rock Creek flows into the Clark Fork River below Noxon Reservoir. Rock Creek is characterized by high velocities and large flow volumes during snowmelt runoff. The creek flows intermittently during baseflow periods, except for short reaches where perennial flow is maintained by alluvial groundwater and discharge from Engle Creek, Orr Creek, and alluvial groundwater from Big Cedar Gulch (Salmon Environmental Services 2012). The perennial flow downstream of Engle Creek is maintained by a bedrock spur about 3,000 feet upstream of MT 200. The bedrock probably prevents surface flow from entering the coarse subsurface alluvium, and may also force alluvial groundwater back into the channel. The surface flow becomes intermittent again when it reaches alluvium about 2,000 feet upstream from MT 200.

The Forest Service has been continuously gaging Rock Creek at RC-2000, located about 100 feet upstream of MT 200, since May 2011 (KNF 2011b, 2014a, 2014b). The estimated bankfull flow is 900 cfs. The highest flow measured was 782 cfs on May 13, 2013. During 2011, 2012 and

2013, streamflows peaked in mid-May. Flows of 100 cfs or greater occurred in 2011 during most days between mid-May and to the first week of July. 2012 and 2013 were wetter years, with flows of 100 cfs or greater starting at the end of March/beginning of April and occurring during most days through early to mid-July. Flows declined to less than 1 cfs or less in 2011 from September 20 through January 4, 2012, in 2012 from September 20 to October 19, and in 2013 from September 4 to September 23. Flows were also low (typically 2 to 5 cfs) in January to early March.

Rock Lake, at an elevation of 4,958 feet, has a 1.43 square mile watershed, a 58-acre surface area, a mean depth of 30 feet, and a maximum depth of 70 feet. The estimated volume of Rock Lake is 1,302 acre-feet (Gurrieri, pers. comm. 2011). Due to the steep, rocky shoreline, Rock Lake has a narrow, rocky littoral zone with very little littoral zone vegetation, based on the agencies' September 2007 site visit and review of aerial photographs. Rock Lake is included in the GDE inventory area described in Appendix C.

Rock Lake is located along the Rock Lake Fault and is fed by a short perennial stream. Water sources include snowmelt (particularly during the spring and early summer), rainfall (particularly in October and November), and groundwater via a shallow flow path during the runoff period and deeper bedrock groundwater throughout the year (Gurrieri 2001). The Rock Lake watershed receives an estimated average 78 inches of precipitation annually (ERO Resources Corp. 2012c). The volume of groundwater inflow to Rock Lake is a small fraction of the annual hydrologic budget; the annual water balance is dominated by surface water (Gurrieri 2001). The residence time of the lake water is very short during the spring snowmelt period (a few days), and lengthens significantly later in the year. The lake is a flow-through system; the lake gains water from surface runoff, from groundwater from the springs above it that flow to the lake, and directly from bedrock groundwater surrounding it. The lake loses water via evaporation, a surface outlet, and possibly groundwater outflow. Stage changes in Rock Lake were measured from mid-June through mid-October in 1999; the total decrease in lake level during that time was 1.29 feet (Gurrieri 2001). Lake stage measurements have been collected occasionally since 1999, and MMC began continuously recording lake stage changes in 2009. The lake measurements show that the lake level generally rises in late April to May as the snowpack melts, begins to decline in August, increases in October, and then remains relatively constant during the winter (NewFields 2013a, MMC 2014d). During the 2009 to 2013 period, the lake level fluctuated by about 2 feet (MMC 2014d).

East Fork Bull River Watershed

The East Fork Bull River has several tributaries that drain an area of about 26 square miles of the CMW. The highest elevation of the East Fork Bull River watershed is 7,940 feet and its lowest elevation is 2,290 feet where it enters the Bull River. Its entire 8-mile length is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012).

In its uppermost ephemeral reaches, the source of water supply to the East Fork Bull River basin is surface water runoff, but where flow becomes perennial at an elevation of about 5,400 feet, flow from a spring (EFBR-10), which may be associated with the Rock Lake Fault, is a source of bedrock groundwater to the stream. St. Paul Lake, elevation 4,715 feet, is located along the Rock Lake Fault near the top of the East Fork Bull River watershed. Five tributaries, one of which runs along the trace of the Rock Lake Fault, flow into the lake. The eastern tributary has two branches, one that originates at 5,589 feet and one that originates at 5,348 feet. Another tributary originates at 5,595 feet and is 2,950 feet in length. The tributaries are primarily bedrock-controlled cascades, with average gradients ranging from 17 to 34 percent (Kline Environmental Research and NewFields 2012). St. Paul Lake is perched on a moraine at the junction of two mountain valleys. The glacial moraine material beneath the lake is very coarse. Outflow from the lake is through the glacial gravels to the East Fork Bull River drainage. Flow resurfaces at a small wetland 330 feet northwest of St. Paul Lake at an elevation of 4,706 feet (Kline Environmental Research and NewFields 2012) (Figure 76).

St. Paul Lake has a 9-acre surface area and a drainage area of 1.5 square miles. The major source of water to the lake is snowmelt. Seasonal stage changes have not been measured in St. Paul Lake; the lake level has been observed to fluctuate to a much greater extent than does Rock Lake due to leakage through the relatively high permeability moraine material (Gurrieri, pers. comm. 2008). St. Paul Lake can become completely dry during extended periods of little to no precipitation.

Below St. Paul Lake, the river is steep (average 12 percent gradient), with rapids and cascades. After the gradient begins to flatten, there are also pools, glides and riffles in the river (Kline Environmental Research and NewFields 2012). Two tributaries that join the East Fork Bull River within the CMW are 1.8-mile long Isabella Creek, and 1.2-mile long Placer Creek. Placer Creek drains a small watershed east of St. Paul Lake, and Isabella Creek drains a larger watershed along the mountain divide. Isabella Lake is small and lies within a closed depression along the crest of the Cabinet Mountains. Isabella Lake has no defined stream channel from the lake to Isabella Creek.

The flow of the East Fork Bull River just upstream of the confluence with the Bull River has been gaged by the Forest Service since May 2009 (KNF 2011c, 2011d, 2011e, 2012b, 2014c). The estimated bankfull flow at the gage is 694 cfs. During the 2009 to 2013 period, streamflows peaked in mid-May, with the highest flow (820 cfs) occurring on May 16, 2011. Peak flows also occurred due to rain-on-snow events that occurred in December 2009 (740 cfs) and January 2011 (672 cfs). During spring runoff, flows exceeding 100 cfs occurred for 22 days in May 2009, from April 20 to July 5 in 2010, from May 5 to July 27 in 2011, from April 12 to July 21 in 2012, and from April 2 to 13 and April 27 to July 6 in 2013. During the period of record, lowest flows (15 cfs or less) occurred in the last week of August, September, and October, and at times during the winter months.

Swamp Creek and Wanless Lake

On the west side of the Cabinet Mountains, Swamp Creek flows 14.7 miles from Wanless Lake to the Clark Fork River. The highest elevation of the Swamp Creek watershed is 7,610 feet and its lowest elevation is 2,350 feet where it enters the Clark Fork River. The creek is rated as substantial (Class 3) for fisheries habitat (FWP 2012). Wanless Lake, elevation 5,100 feet, is slightly larger than Rock Lake, has a slightly larger watershed with similar topography, is located within the Revett Formation, and is bisected by the Rock Lake Fault. Swamp Creek and Wanless Lake are outside the area of predicted effects from mining, and would be used as benchmark monitoring sites (see Appendix C, Section C.10).

Copper Gulch

Copper Gulch flows 4.6 miles to Bull River. Its entire length is rated as outstanding (Class 1) for fisheries habitat by the FWP (FWP 2012). The highest elevation in the watershed is 7,714 feet and the lowest elevation is 2,270 feet where it enters the Bull River. Channel stability in the lower reach has been adversely affected by extensive stream channelization and subsequent channel maintenance. Factors affecting fish habitat included stream channelization, riparian alteration, channel clearing, and the high gradient nature of the drainage. The lower reach upstream of the confluence with Bull River is subject to seasonally intermittent flows. Copper Gulch may be used for bull trout mitigation. The agencies expect that the streamflow and water quality in Copper Gulch would not be affected by the mine or transmission line, and it is not discussed further in this section.

3.11.3.2.2 Streamflow

Instantaneous and Continuous Streamflow Measurements

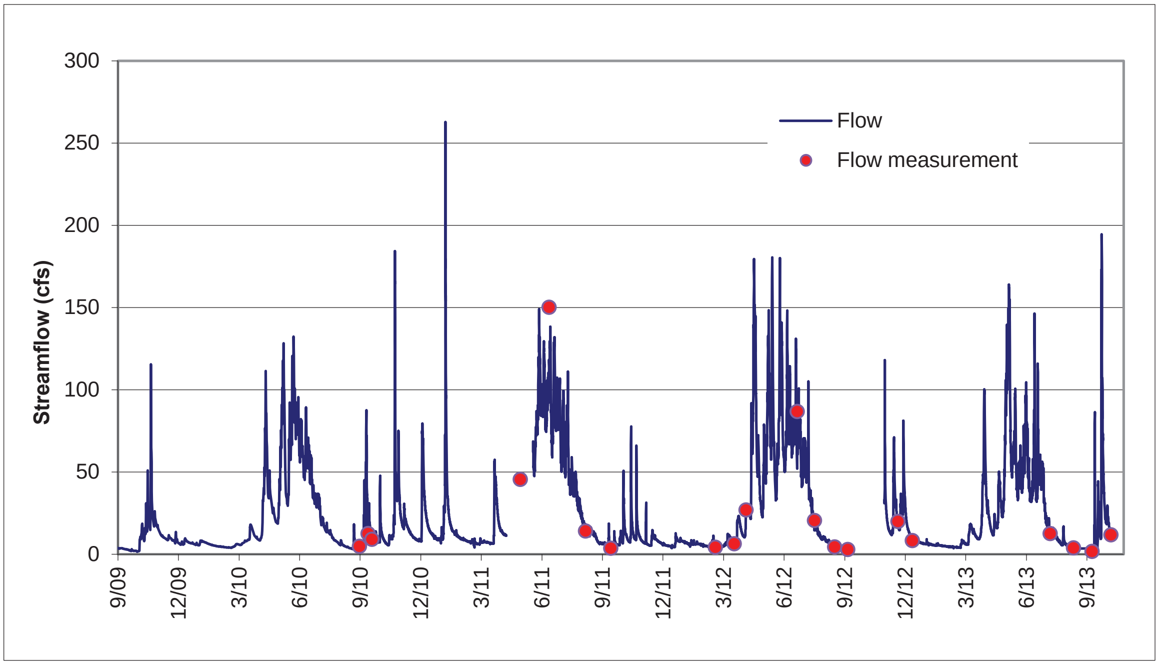
Instantaneous and continuous streamflow in the analysis area has been collected using a flow meter at measured stream cross-sections, mostly at lower elevations and outside of the CMW. None of the streams within the analysis area have been continuously gaged on a long-term basis; without such data, hydrographs cannot be developed to determine baseflow, average low flow, or peak flow.

In all of the streams measured (Libby Creek, Ramsey Creek, Poorman Creek, Little Cherry Creek, Bear Creek, Miller Creek, West Fisher Creek, Rock Creek, and the East Fork Bull River), the highest annual flows typically occur between April and June, with the highest flows most often occurring in May, then secondly in April. There are typically smaller, short-term increases in streamflow in October through March due to precipitation and snowmelt events. Lowest flow occurs most often from mid-August to mid-September and may occur for up to 2 months during late summer to early fall and also may occur during November through March. Streamflow in the analysis area was often not measured during November through February. Other streamflow peaks occurred in the spring and early summer of 2010 as a result of both precipitation and snowmelt runoff. Highest and lowest measured flows are provided for each stream in Table 104. Some of the lowest measured flows were close to or lower than the lower range of estimated $7Q_{10}$ flow shown in Table 86 in section 3.8.3.

The analysis area is sometimes subjected to strong warm-frontal storms between November and mid-April that bring heavy rain, warm temperatures, and strong winds. Rain-on-snow events occur about every 6 years east of the Cabinet Mountain divide (Wegner, pers. comm. 2006c) and every year on the west side of the Cabinet Mountains (Neesvig 2010). Depending on storm intensity and soil and snowpack moisture conditions, these storms can produce very high streamflow. For example, a major rain-on-snow event occurred in December 2004. The KNF measured a flow of 560 cubic feet per second (cfs) at the West Fisher Creek site and a flow of 549 cfs in Libby Creek at US 2 (Wegner, pers. comm. 2006d). In addition to causing high streamflow, channel migration, and the movement of large materials within the stream channels, the high rate of water to the soil can generate unstable conditions on hill slopes. During such high flows, landslides can occur and stream channels may be altered by bank erosion, down cutting, and redistribution of sediment and large woody debris. These events caused extensive damage to road drainage and stream crossing structures throughout the KNF. Channel alterations caused by ice flows associated with these events occurred to most stream systems in the analysis area and resulted in streambed scouring. The rain-on-snow event that occurred in February 1996 resulted in down cutting of most perennial channels by about 2 to 3 inches.

Beginning in September 2009, MMC began continuously measuring stage in Libby Creek at LB-200, upstream of the Libby Adit. The stage readings were used to develop a stage-discharge relationship at LB-200; the resulting streamflows are provided in Chart 18. At LB-200, large precipitation events in October 2009, November 2010, January 2011, and September 2013 increased streamflow significantly during a typically low-flow period.

Chart 18. Streamflow at LB-200, September 2009 to October 2013.



Source: MMC 2014d.

The estimated $7Q_{10}$ flow at LB-200 using the USGS method is 2.35 cfs, with an estimated range of 1.11 cfs to 5.05 cfs. Measured flow averaged less than 2.35 cfs for seven consecutive days between October 5, 2009 and October 14, 2009. The lowest 7-day average flow was 1.90 cfs on October 14. Based on the Poorman SNOTEL site, 2009 was the driest year in the past 10 years in the project area (Natural Resources Conservation Service 2014).

At LB-2000, numerous streamflow measurements were collected between 1988 and 2009. Flows during all months were very variable, with low flows of 2 cfs or less occurring every month, average monthly flows ranging from 4 cfs in September to 80 cfs in May, and maximum monthly flows ranging from 23 cfs in September to nearly 420 cfs in June. Flows exceeding 200 cfs occurred infrequently; seven measurements greater than 200 cfs occurred in April through June, and one occurred in February.

In September 2012, MMC measured flow in Ramsey Creek 500 feet above the CMW boundary (RC-10) and 4,000 feet downstream of the boundary (RC-20). Flow was 1.15 cfs at the upper location and 1.59 cfs at the lower location. In 2013, MMC measured flow at RC-10 in August, September and October; flows ranged from 1.40 cfs in September to 4.02 cfs in October (MMC 2014d).

Table 104. Measured High and Low Flows in Analysis Area Streams.

Stream	Station	Sampling Period	Minimum Measured Streamflow (cfs)	Maximum Measured Streamflow (cfs)	Number of Measure-ments
Libby Creek	LB-100	4/88 to 10/13	0.77	50.7	32
	LB-200[†]	4/88 to 10/13	0.77	262	Numerous

[†]LB-200 water level stage measured continuously by MMC beginning September 2009.
[£]LB-300 flow includes discharge from the Libby Adit between 1990 to 1998 and 2008 to present. Flow at other Libby Creek sites downstream of LB-300 also may have been influenced by discharge from the adit during the same time periods.
[§]LB-3000 flow measured with a continuous recorder in 1988 and 1989.
[‡]The KNF measured flow at the US 2 bridge until September 2009. The monitoring station was moved about 2 miles downstream due to safety concerns. The new station is outside of the analysis area.
Station locations are shown on Figure 76.
cfs = cubic feet per second; < = less than.
Source: NewFields 2013a; MMC 2008, 2009b, 2010, 2011b, 2012g, 2013; Neesvig, pers. comm. 2006, 2010 and 2011; Wegner, pers. comm. 2006d; Boyd, pers. comm. 2010.

In July to October 2013, MMC measured flow in the upper East Fork Bull River at EFBR-50 monthly measured stage continuously using a pressure transducer (MMC 2014d). The flow ranged from 0.02 cfs in mid-September to 0.22 cfs in mid-October. The transducer data showed a drop in stream stage from July through early September, with a couple of short increases during that period due to precipitation events. The stream stage was lowest in early September, and remained fairly steady for about two weeks, so the flow of 0.02 cfs may represent baseflow conditions. In mid-September, stream stage increased due to fall precipitation. MMC measured a flow of 0.05 cfs in August 2013 at EFBR-10, located at an elevation of 5,400 feet upstream of EFBR-50 where flow was observed to begin in that channel. MMC also measured flow in three of the four other channels that flow into St. Paul Lake in September 2013. Flow in SPL-1, SPL-4, and SPL-11 ranged from 0.01 to 0.03 cfs; these flows may represent baseflow conditions.

MMC installed a pressure transducer in the East Fork Rock Creek at EFRC-100 (inflow to Rock Lake) in August 2013. The continuous stage measurements were fairly steady through mid-September, which may represent baseflow conditions, which was measured in mid-September 2013 as 0.05 cfs. Stream stage increased in mid-September due to fall precipitation.

MMC measured the flow at the outlet of benchmark lake Wanless Lake to Swamp Creek (in Sanders County) in July, August and September 2013. The site (WL-2) is a benchmark monitoring site (outside the range of influence of expected mine or adit inflows) comparable to EFRC-200, the outlet of Rock Lake. The flow at EFRC-200 was measured within 1 to 2 days of flow measurements collected at WL-2, and were similar. Highest flows (5.3 cfs at EFRC-200 and 5.7 cfs at WL-2) were measured in mid-July 2013, and lowest flows (0.3 cfs at EFRC-200 and 0.4 cfs at WL-2) were measured in mid-September 2013.

MMC also measured flow in Swamp Creek (in Lincoln County) at the proposed wetland mitigation site adjacent to US 2. Flow measurements collected at three locations at the site between May and September 2011 and June and August 2012 ranged from 1.37 in September to 31.8 cfs in May. Flow in a tributary channel from a spring (#2) ranged from 6.19 cfs in May 2011 to 1.01 cfs in August 2012 (NewFields 2013a).

Synoptic Streamflow Measurements

MMC completed synoptic streamflow measurements in late August 2005 at selected locations along Ramsey Creek, Poorman Creek, Little Cherry Creek, and Libby Creek (Table 105). These data indicate that the three tributaries to Libby Creek along nearly all of their reaches are gaining streams with inflow from groundwater. Some of the flow in Libby Creek between stations LB-500 and LB-800 apparently infiltrates into the alluvium, because the increase in flow from 1.6 to 2.8 cfs does not account for the 2.8 cfs coming in from Ramsey Creek (RA-600) and unknown flow from Howard Creek. Libby Creek below LB-800 apparently gains some flow from groundwater.

Table 105. August 2005 Synoptic Streamflow Measurements.

Ramsey Creek	Poorman Creek	Little Cherry Creek	Lower Libby Creek
RA-1 = 1.79	PM-500 = 1.07	LC-100 = 0.16	LB-500 = 1.55
RA-2 = 1.93	PM-1 = 0.76	LC-1 = 0.17	LB-800 = 2.82
RA-3 = 2.26	PM-2 = 1.03		LB-2000 = 8.86
RA-4 = 2.34	PM-3 = 1.5	LC-100 = 0.11*	
RA-600 = 2.79	PM-4 = 0.91	LC-1 = 0.33*	
	PM-1000 = 0.77	LC-800 = 1.82*	
	PM-5 = 1.93		
		LC-1 = 0.37**	
		LC-800 = 0.31**	

All flows are in cubic feet per second.
Measurements made August 24-26, 2005, except data with (*) measured June 25-26, 2005 or data with (**) measured July 30-31, 2005.
Source: Geomatrix 2006b.

On September 3, 2010, MMC completed synoptic flow measurements along Libby Creek from the top of the main channel where the uppermost channel from the west joins the uppermost channel from the south, about 1 mile upstream of the CMW boundary to LB-200 (Chart 19). MMC also completed synoptic flow measurements in this same area in September and October 2012, and extended the measurements up to the top of the highest, most westerly channel up to an elevation of 5,880 feet (Figure 76). MMC completed synoptic flow measurements from LB-40 to LB-100 in July through October 2013. The 2012 and 2013 synoptic flow measurements are provided in Table 106. LB-300 was not included in the synoptic flow measurements of upper Libby Creek. This entire section of the Libby Creek channel is narrow, with numerous steep side

Chart 19. Flow in Upper Libby Creek, September 2010.

Table 106. 2012 and 2013 Synoptic Streamflow Measurements in Upper Libby Creek.

Measurement Date	LB-40	LB-30	LB-20	LB-50	LB-70	LB-80	LB-100	LB-200
9/13/12	0.18	0.54	0.30	1.67	1.37	1.40	3.87	2.78
9/27/12	0.14	0.29	1.66	1.87	1.08	1.77	2.33	NM
10/10-14/12	0.02	0.37	0.25	0.85	0.15	0.61	1.92	NM
7/10/13	3.34	5.52	1.55	10.88	13.16	10.53	19.70	12.57
8/7/13	1.39	2.05	0.87	4.83	4.31	3.19	7.40	5.27
9/4/13	0.33	0.73	0.57	2.67	2.00	1.24	2.39	NM
10/4-7/13	1.86	3.27	1.21	6.67	12.12	13.46	25.90	24.83

All flows are in cubic feet per second. LB-20 and LB-30 are tributaries to the mainstem of Libby Creek between LB-40 and LB-50.
NM = No measurement.
Source: MMC 2014d.

channels on both sides of the creek. At 5,880 feet, in an area of extensive colluvium and rock talus, the flow in the channel was measured at 0.02 cfs in September 2012. Perennial flow in Libby Creek originates slightly above LB-50 where a fault of the Snowshoe thrust cuts across the valley (Fillipone and Yin 1994). At most locations measured in the mainstem, the creek showed flow gains except at the last location at LB-200.The creek for the most part gains flow from above LB-50 to LB-100, then loses flow between LB-100 and LB-200. Measurements indicate that some water is lost to alluvial deposits between LB-100 and LB-200, and that the alluvium is limited in the volume of water it can carry.

Downstream of LB-200, at least five steep side channels enter the main channel of Libby Creek between LB-200 and LB-300. The Libby Creek channel does not begin to widen and become flatter until the Libby Adit site just above LB-300. Historical flow data (1989-2013) for LB-200 and LB-300 collected on the same date show that during low flows (defined for this purpose as flow of less than 4.63 cfs, the estimated $7Q_2$ flow at LB-300), the stream gained an average 36 percent in flow between LB-200 and LB-300. Based on these data, upper Libby Creek to LB-300 is largely a gaining stream, with inflow from groundwater (either directly to the mainstem or via the numerous side channels), and a temporary loss to alluvium of limited thickness within the narrow channel above LB-200. This water appears to return to the creek between LB-200 and LB-300.

3.11.3.3 Spring Flows

Numerous springs occur in the analysis area and are discussed in section 3.10, *Groundwater Hydrology*.

3.11.3.4 Stream Channel Characteristics of Impoundment Sites

3.11.3.4.1 Little Cherry Creek Tailings Impoundment Site

At the Little Cherry Creek Tailings Impoundment Site, the Little Cherry Creek channel substrate material is predominantly gravel. The average bankfull width of upper Little Cherry Creek is 8 feet and 14 feet in the lower creek. The maximum bankfull depth is 0.7 to 1.2 feet. The floodplain width ranges from 30 to more than 100 feet. The channel gradient ranges from 7 percent near the confluence with Libby Creek to 2 percent in the upper part of the watershed (Kline

Environmental Research 2005a). The channel is stable, and the stream contains pools and riffles. Bedrock outcrops in the channel downstream of the Seepage Collection Dam Site. The range of measured Little Cherry Creek flows is provided in Table 104.

3.11.3.4.2 Poorman Tailings Impoundment Site

Surface water in four drainages in the Poorman Tailings Impoundment Site (Drainages 3, 5, 10 and 14) flows east toward Libby Creek (Figure 87). The four drainages comprise a small, 1,025-acre watershed within the Libby Creek watershed. Libby Creek is a third-order stream. The area upstream of and including the watershed of the four unnamed drainages is 23,245 acres. Major tributaries of Libby Creek upstream of the Poorman Tailings Impoundment Site are Poorman Creek, Ramsey Creek, Howard Creek, and Midas Creek. The four drainages were characterized by Kline Environmental Research (2012). The descriptions below apply to observations made in May and September 2011.

Drainage 3

Drainage 3 originated from two main branches (Figure 87). The flow path from a wetland (WUS 2) and a spring (SP-28) and a spring slightly downgradient in one of the branches had minor flow when measured in May 2011. The flow path transitioned from unchannelized with flow in May 2011 to channelized with flow in September 2011. The second main branch also originated in a wetland (WUS 1). From WUS 1, the flow path was mainly unchannelized, with short reaches where it was channelized, with a transition to a mainly persistent flow near the confluence with the other main branch. The combined flows in the second branch created a channel with persistent flow for most of the distance to Libby Creek. Of the four drainages, Drainage 3 had the highest measured discharge (202 gpm) to Libby Creek when measured in May 2011.

Drainage 5

Drainage 5 originated from two branches (Figure 87). Flow in one of the branches is entirely unchannelized. Flow began upstream of Spring 31, flowed through a wetland (WUS-36), drained through a culvert (NFS road #6212H), and continued through dense alder before merging with a second branch. The second branch began at Spring 32, flowed through channel habitat, then became unchannelized. The second branch was joined by flow from Spring 30 and entered wetland WUS-4. This wetland had standing water in May and September 2011. Flow through the culvert at NFS road #6212H ceased in October. Below the culvert, flow became somewhat dispersed through a dense stand of alder, where it joined with the other branch.

After the two branches combined, the channel became entrenched and crossed a low-gradient, bushy area before cascading down a steep bank in a narrow v-shaped valley. It then flattened out and ended abruptly at a pool near the edge of the proposed Seepage Collection Pond in Alternative 3. Flow to the terminal pond appeared to be perennial. From the terminal pool, there was no evidence of surface flow connecting Drainage 5 to Libby Creek.

Drainage 10

The three branches in Drainage 10 were largely unchannelized. Flow in Drainage 10 originated at springs 33, 34, and 35. the lower portion of the main branch dropped steeply through a narrow, v-shaped valley, forming step pools, step riffles, and cascades, followed by a riffle-dominated final reach. The drainage became unchannelized across a flat area leading to two culverts under NFS road #1408. The flow dispersed and infiltrated in this flat area and did not always reach the culverts. Kline Environmental Research (2012) assumed that Drainage 10 connected to Libby Creek downgradient of the culvert.

Drainage 14

All of the flowing reaches of Drainage 14 were in the upper part of the drainage. Segments of channelized flow were scattered throughout the drainage. Four springs (37, 38, 39, and 40) contributed water to the channel. Several reaches of Drainage 14 below the upper reaches were only identifiable during spring runoff. The lowest reach of Drainage 14 within the disturbance boundary was channelized in a well-defined valley. Surface flow at the downstream disturbance boundary was assumed to reach Libby Creek.

3.11.3.5 Climate Change

The USDA Forest Service issued the KIPZ Climate Change Report in 2010 (USDA Forest Service 2010a). The Department of the Interior, Bureau of Reclamation issued three reports on climate change in 2011 (Reclamation 2011a, 2011b, 2011c), discussed in section 3.3.1, *Climate Change* and in section 3.10.3.4, *Climate Change* in the *Groundwater Hydrology* section. For the Columbia River Basin in general, warming is expected to diminish the accumulation of snow during the cool season (i.e., late autumn through spring) and the availability of snowmelt to sustain runoff during the warm season (i.e., late spring through early autumn). Increased rainfall in December through March is expected to increase runoff during those months. Decreased snowpack volume could result in decreased groundwater infiltration, decreased spring/summer runoff, increased rain-on-snow events, and ultimately decreased contribution to baseflow in streams (USDA Forest Service 2010a; Reclamation 2011c).

3.11.4 Environmental Consequences

3.11.4.1 Alternative 1 – No Mine

Under this alternative, MMC would not develop the Montanore Mine. Any existing exploration-related or baseline collection disturbances by MMC would be reclaimed in accordance with existing laws and permits. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Reduction of streamflow in Libby Creek above the Libby Adit from the partial dewatering of the Libby Adit would continue until the Libby Adit was plugged and groundwater levels recovered. Streamflow below the Libby Adit would not be affected.

3.11.4.2 Effects Analysis of the Action Alternatives

Mine facilities and activities in Alternatives 2, 3 and 4 would affect streamflow and the volume and level of Rock Lake. All mine alternatives would reduce groundwater discharge to area streams and Rock Lake due to mine and adit inflows and lowering of the potentiometric surface during all five mine phases (Evaluation, Construction, Operations, Closure and Post-Closure). When the potentiometric surface reached steady state conditions after mining ceased, the effect would vary by drainage and without or with mitigation. Without mitigation, the effect on streamflow in the East Fork Rock Creek and East Fork Bull River and on the volume and level of Rock Lake would be the same in all mine alternatives. The effects on aquatic life and habitat due to streamflow changes are described in Section 3.6, *Aquatic Life and Fisheries.* The indirect effects due to streamflow changes on riparian vegetation are described in Section 3.22, *Vegetation*, and on wetland vegetation are described in Section 3.23, *Wetlands and Other Waters of the U.S.* Various mitigations of effects on surface water may be used and are described in sections 2.5.4.3.2, 3.10.4.3.3 or 3.11.4:

- Mitigation modeled by MMC in the 3D model, which is the grouting of the side of the mine blocks which are adjacent to the Rock Lake Fault This grouting would occur on the three uppermost mine blocks and corresponding access ramps during operations
- Maintaining one or more barrier pillars, if necessary, in the mine during operations and constructing bulkheads at the access openings at Closure
- Increasing the buffer zones near Rock Lake and the Rock Lake Fault
- Additional grouting along the Rock Lake Fault
- Mitigation of effects on senior water rights in the Libby Creek watershed during Construction, Operations, Closure, and Post-closure

3.11.4.3 Alternative 2 – MMC Proposed Mine

In MMC's proposal, the mill and production adits would be located in the upper Ramsey Creek drainage, about 0.5 mile east of the CMW boundary. An additional adit on MMC's private land in the Libby Creek drainage and a ventilation adit on MMC's private land east of Rock Lake would be used for ventilation. A tailings impoundment would be constructed in the Little Cherry Creek drainage, and would require the diversion of Little Cherry Creek. Two LAD Areas between Poorman Creek and Ramsey Creek are proposed to allow for wastewater discharge using sprinklers during the growing season. A portion of the waste rock produced by driving the adits may be stored temporarily at LAD Area 1, and at the Libby Adit Site, before use in construction.

3.11.4.3.1 Evaluation and Construction Phases (Years 1 through 5)

Streamflow—West Side Streams

Low Flow

Stream baseflow is predicted to change during the Evaluation and Construction Phases (Geomatrix 2011a). At the end of the Evaluation and Construction Phases, streamflow reductions would be 3 percent or less in the East Fork Rock Creek and East Fork Bull River. Effects of Alternative 2 would be the same as Alternative 3 without mitigation.

Streamflow—East Side Streams

Low Flow

Libby, Ramsey, and Poorman Creeks. In Alternative 2, MMC proposes to use slow rate land application for primary treatment of wastewater (Geomatrix 2007b; MMC 2008). Land application is the uniform application (usually with sprinklers) of wastewater to a vegetated soil surface, with no runoff. The discharged water can receive significant treatment as it flows through the plant root/soil matrix (Environmental Protection Agency 2006b). Water discharged to the LAD Areas would either evapotranspire or percolate to groundwater. Water that percolated to groundwater would flow downgradient to the nearest stream. Land application would occur only during the 6-month growing season. The application rate would be adjusted to meet MPDES permitted effluent limits set for discharges at the LAD Areas and to prevent the development of springs in or downgradient of the LAD sites. The discharges to streams from the LAD Areas would be small

(32 gpm or 0.07 cfs); the flow of water initially through groundwater would dampen any sudden increases in streamflow due to the additional water. When land application was used in Alternative 2, increases in flow due to treated water discharges would be less than in Alternative 3 because much of the water discharged at the LAD Areas would evaporate or be used by plants.

Effects of mine inflows on the low flows of east side streams would be similar to Alternative 3. Construction Phase effects for Alternative 3 are shown in Table 108. In Alternative 2, the adits would be in two drainages (Libby and Ramsey creeks), and total water inflow into the adits would be greater in Alternative 2 than Alternatives 3 and 4. Compared to Alternatives 3 and 4, effects on streamflow in Libby Creek above LB-300 would be slightly less and would be slightly greater on Ramsey Creek. Discharges during both phases would increase low flow below LB-300. Discharges from the LAD Areas reaching Ramsey, Libby and Poorman creeks would partially offset streamflow effects from mine dewatering.

MMC did not propose in Alternative 2 to discharge water whenever flow at LB-2000 was less than 40 cfs to avoid adversely affecting senior water rights. When water was stored for mill startup during the Construction Phase, low flow at and downstream of LB-300 would be substantially less in Alternative 2 than Alternatives 3 or 4.

Little Cherry Creek. Little Cherry Creek would not be affected during the Evaluation Phase. After the Diversion Dam was constructed during the Construction Phase, water in Little Cherry Creek above the tailings impoundment would be diverted around the tailings impoundment down to Libby Creek via a 10,800-foot-long Diversion Channel. The channel would be sized to divert large flood flows safely around the tailings impoundment. The Diversion Channel would consist of an upper channel, and two existing natural drainages. Two natural drainages would be used to convey water from the upper channel to Libby Creek. The northern drainage (Drainage 10) is currently a 9,000-foot long intermittent drainage that is primarily unchannelized in the upper part and has perennial channelized segments interspersed with unchannelized wet and dry segments in the lower part. The southern drainage (Drainage 5) is about 3,000 feet long with similar characteristics to Drainage 10. Flow in Drainage 5 does not appear to reach Libby Creek (Kline Environmental Research 2012). During the Construction Phase, the flow in Drainages 5 and 10 would increase.

Surface water within the catchment area of the Seepage Collection Dam and within the tailings impoundment area would be captured and returned to the mill for ore processing. Below the Seepage Collection Dam, the source of water to the former Little Cherry Creek channel would be surface water runoff from the catchment area and groundwater discharge below the Seepage Collection Dam.

Bear Creek. Low flow in Bear Creek would not be affected during the Evaluation or Construction Phases.

Peak and Average Annual Flow

The KNF's ECAC model results (KNF 2012a) indicates timber clearing for the mine facilities in Ramsey Creek may measurably increase the peak flow of the creek (Appendix H). The increase in Ramsey Creek peak flow is estimated to be 8 percent. When coupled with the MMC's proposed transmission line alternative (Alternative B), mine-related water yield increase would reach a measurable level in Ramsey and Poorman creeks. According to Grant *et al.* (2008), changes in peak flow that fall in a range of ±10 percent are within the error of peak flow measurement and cannot be ascribed as an effect. Based on an analysis of streamflow data from streams with gaging stations located at the periphery of the analysis area on the KNF, the average variability in low flow values is 20 percent (Wegner 2007). Increased peak flows as a result of timber clearing in other streams in Alternative 2 and in combined Mine-Transmission Line Alternative 2B would be less than 10 percent. Discharges of mine and adit inflows would slightly increase peak flow (less than 1 percent) and average annual flow (about 5 percent) at LB-300. The percent increase in average annual flow below LB-300 would be less as flow increases downstream.

Rock Lake

The effect on Rock Lake volume and levels would be the same as Alternative 3 without mitigation.

Stream and Floodplain Crossings

Alternative 2 would require three new road crossings across perennial streams and one new road crossing across a non-perennial stream (Table 107). The Ramsey Plant Site would affect less than 0.1 acre of FEMA-designated 100-year floodplain on Ramsey Creek. During construction, disturbances within the FEMA-designated 100-year floodplain would be minimized. New bridges are proposed over Ramsey and Poorman creeks and a culvert would be installed in Little Cherry Creek above the Diversion Dam. For all alternatives, no designated 100-year floodplains would be crossed by new roads. After construction is completed, the bridges and culvert would not affect natural streamflow.

Table 107. Comparison of Stream and Floodplain Crossings Required for Mine Alternatives.

Mine Alternative	Number of Stream Crossings by New Roads		Disturbance Area within a FEMA-Designated 100-year Floodplain (acre)
	Perennial Stream	Other Streams	
2	3	1	<1
3	1	1	9
4	2	1	3

< = less than.
Source: GIS analysis by ERO Resources Corp. using KNF data.

An estimated 12,600 feet of the Little Cherry Creek floodplain would be inundated by construction of the tailings impoundment and seepage collection pond. A new floodplain would be created along the diverted Little Cherry Creek channel and the floodplain of Drainage 10 may widen with increased flows. The net floodplain loss would be 9,510 feet in the Little Cherry Creek watershed.

3.11.4.3.2 Operations Phase (Years 6 through 25)

Streamflow—West Side Streams

Low Flow

The effect on west side streams would be greater than during the Construction Phase, and the greatest effect during the Operations Phase would be at the end of mining operations. The effect would be the same as Alternative 3 without mitigation (Table 110). For the two west side aquatic life sites (RC-3 and EFBR-2), the effect would be the same as Alternative 3 without mitigation (Table 109).

Streamflow—East Side Streams

Low Flow

Libby, Ramsey, and Poorman Creeks. The effect of mine inflows on east side streams would be greater than during the Construction Phase, and the greatest effect during the Operations Phase would be at the end of mining operations. MMC did not propose in Alternative 2 to discharge water during operations whenever flow at LB-2000 was less than 40 cfs to avoid adversely affecting senior water rights. The water balance for Alternative 2 indicates that up to 159 gpm of additional water on an annualized basis would be required during the Operations Phase to meet mill needs (Table 14 in Chapter 2). Flow at and downstream of LB-300 would be less in Alternative 2 than Alternatives 3 or 4. The effect on Ramsey Creek would be slightly greater in Alternative 2 because the adits in Ramsey Creek drainage would affect streamflow in Ramsey Creek and less in upper Libby Creek (Table 110). The effect on Poorman Creek would be only from mine inflows (a loss of 0.01 cfs without mitigation and no effect with MMC's modeled mitigation). The pumpback wells and impoundment diversions would not affect Poorman Creek in Alternative 2.

Little Cherry Creek. The agencies completed an analysis of the effect of Alternative 2 to the Little Cherry Creek watershed area and the resulting change in the flow of area streams (ERO Resources Corp. 2010a in Appendix H). Precipitation and runoff captured by the tailings impoundment and the Seepage Collection Dam would no longer flow to either the diverted or former Little Cherry Creek. During operations, 13 percent of the Little Cherry Creek watershed would continue to contribute flow to the former Little Cherry Creek channel downstream of the Seepage Collection Dam; the estimated average annual flow would be 0.77 cfs. The flow in Drainage 10 would be about 60 percent of the flow of the original Little Cherry Creek. The estimated $7Q_{10}$ flow of the water diverted to Drainages 5 and 10 would be 0.16 cfs. Diversions, combined with the pumpback well system would likely eliminate the $7Q_{10}$ flow in the diverted Little Cherry Creek and substantially reduce the $7Q_2$ flow. Flow below the Seepage Collection Dam in the former Little Cherry Creek channel would also be substantially reduced. The flow in Drainages 5 and 10 (the diverted Little Cherry Creek) would increase. Some of the flow would be intercepted by the pumpback well system.

Bear Creek. Low flow in Bear Creek would be reduced during the Operations Phase by diversions and a pumpback well system at the Little Cherry Creek impoundment. The effect was not quantified.

Peak and Average Annual Flow

The effect on peak flow in Ramsey Creek from timber harvesting for mine facilities would continue during the Operations Phase. Other than Ramsey Creek, the effect on peak and average annual flows in the Libby Creek watershed would be negligible. Appropriation of water for mill use would be taken when the flow of Libby Creek was equal to or greater than the average annual low flow of the creek at a rate of up to 159 gpm (0.35 cfs), which would reduce peak flow and average annual flow in Libby Creek at the point of diversion (about LB-2000).

Rock Lake and Rock Creek Meadows

The effect on Rock Lake volume and levels and the effect on Rock Creek Meadows would be the same as Alternative 3 without mitigation.

3.11.4.3.3 Closure Phase (Years 26 to 30)

Streamflow—West Side Streams

The effects during the Closure Phase would be the same as Alternative 3 without mitigation.

Streamflow—East Side Streams

Low Flow

Libby, Ramsey, and Poorman Creeks. After the adits were plugged at the surface as proposed in Alternative 2, reduction in low flow above the Libby Adit Site (LB-300) and above lower Ramsey Creek (RA-600) would be slightly greater than predicted during the Operations Phase, with the greatest reductions occurring immediately after the adits were plugged. The effect was not quantified. Compared to Alternative 3, effects above LB-300 would be slightly less and above RA-600 would be slightly greater. Discharges during both phases would increase streamflow downstream of the LAD Areas and Water Treatment Plant discharge. Discharges would partially offset streamflow effects from mine dewatering during low flows. Overall streamflow increases due to discharges would be less than in Alternative 3 because some water would evaporate at the LAD areas. The effect on flows in Poorman Creek during this phase would be negligible.

Little Cherry Creek and Bear Creek. The effect on Little Cherry Creek and Bear Creek would be the same as during the Operations Phase.

Peak and Average Annual Flow

After site reclamation, the increase in peak flow in Ramsey Creek would be less than during operations as disturbed areas became revegetated. The effect of discharges and vegetation clearing on other streams would be the same as during the Construction Phase. MMC did not propose any diversions from Libby Creek except as needed during the Operations Phase.

Rock Lake and Rock Creek Meadows

The effect on Rock Lake volume and levels and on Rock Creek Meadows would be greater than during the Operations Phase. The effect during the Closure Phase was not quantified and would be the same as Alternative 3 without mitigation.

3.11.4.3.4 Post-Closure Phase (Years 31+)

Streamflow—West Side Streams

Low Flow

The effect on west side streams would increase from the Operations and Closure Phases and would be the greatest during the Post-Closure Phase after the end of mining operations in the East Fork Rock Creek, Rock Lake, and the East Fork Bull River. The effects would be the same as described for Alternative 3 (Table 112 and Table 113).

Streamflow—East Side Streams

Low Flow

Libby, Ramsey, and Poorman Creeks. The effect would be the same as Alternative 3 without mitigation except that the effect on Ramsey Creek would be slightly greater (Table 112 and Table 113).

Little Cherry Creek and Bear Creek. After the impoundment was reclaimed and runoff was no longer subject to ELGs and applicable water quality standards, runoff from the reclaimed tailings impoundment surface and the watershed west of the impoundment would be routed toward Bear Creek. Because the impoundment would be reclaimed, runoff would be stormwater not mixed with any mine drainage or process water. The Bear Creek watershed area where runoff would meet the creek would increase by 560 acres, an 8 percent increase (ERO Resources Corp. 2010a). Watershed area and mean annual precipitation were the location-specific variables in the equations developed by the USGS to estimate both $7Q_2$ and $7Q_{10}$ flow in the region that includes the analysis area (Hortness 2006). Assuming no change in annual precipitation, the Hortness method would predict that an 8 percent increase in watershed area would increase $7Q_2$ and $7Q_{10}$ flow by about 8 percent. At closure, the reclaimed impoundment surface would drain toward Bear Creek and the reclaimed impoundment would be in a watershed adjacent to the original watershed (Little Cherry Creek). Some of the precipitation that would infiltrate into the reclaimed impoundment would be intercepted by the impoundment's underdrain system and routed toward Little Cherry Creek, the original watershed. Consequently, the Hortness method overestimates $7Q_2$ and $7Q_{10}$ flow in watersheds containing the reclaimed impoundment. Both $7Q_2$ and $7Q_{10}$ flow likely occur during late summer or early fall during periods of little or no precipitation. The amount of baseflow that would flow during these period toward Bear Creek would be negligible. The agencies anticipate little or no increase in $7Q_2$ and $7Q_{10}$ flow in Bear Creek. Any increased flow would partially offset the flow reduction caused by the pumpback well system as long as it operated. The effect of the pumpback well system on Bear Creek was not quantified.

Low flows in the diverted Little Cherry Creek and Drainage 10 would likely be substantially reduced as long as the pumpback well system operated. When the impoundment was reclaimed and the pumpback well system no longer operated, the watershed of the former Little Cherry Creek would be 220 acres larger than during the Operations Phase, but would remain 74 percent smaller than the existing creek. The effect of a smaller watershed would be less than the Hortness method would predict based on watershed size because some of the water intercepted by the impoundment's underdrain system would flow to the former Little Cherry Creek. The diverted creek's watershed (Drainage 10) would be 45 percent smaller than the existing Little Cherry Creek's watershed.

Peak and Average Annual Flow

During the Post-Closure Phase, peak flow in Ramsey Creek would gradually return to pre-mine conditions as disturbed areas became revegetated. The agencies estimate the Ramsey Creek watershed would take 25 years after completion of the Closure Phase to recover to existing peak flow conditions. The average annual flow in Bear Creek would be an estimated 8 percent higher over the long term. The watershed of diverted Little Cherry Creek would be 915 acres, or 54 percent smaller than the original Little Cherry Creek. Average annual flows of diverted Little Cherry Creek are estimated to be about half of the original creek flows. The former Little Cherry Creek channel below the impoundment dam would have a watershed of 445 acres (ERO Resources Corp. 2010a in Appendix H), providing some flow to the channel. In addition, Klohn

Crippen (2005) estimated at steady state 50 to 100 gpm from the impoundment's underdrain system would flow toward the former Little Cherry Creek. Following cessation of the pumpback wells and recovery of groundwater levels, springs and seeps outside of the impoundment footprint that were affected by the pumpback wells would likely return to pre-mine conditions and also may contribute to baseflow. The effect of discharges and vegetation clearing on other streams would be the same as during the Construction Phase. After discharges ceased, peak flow and average annual flow would return to pre-mine conditions.

Rock Lake and Rock Creek Meadows

The effect on Rock Lake volume and levels and on Rock Creek Meadows would be the same as Alternative 3 without mitigation and is discussed in section 3.11.4.4.4 *Post-Closure Phase.*

3.11.4.3.5 Climate Change

Due to the range in possible effects of climate change on the water resources and the many factors that could affect that outcome, quantifying the impacts of climate change was not feasible. It is difficult to predict how the hydrologic systems in the Montanore Project analysis area would respond to the forecasted regional effects of climate change. Uncertainty is discussed in section 3.10.4.2.3, *Climate Change*.

The Forest Service (2010a) and the Bureau of Reclamation (2011c) predicted that more precipitation may fall as rain in December through March, resulting in more runoff in the winter, and reduce the accumulation of snow in the winter. Climate change may also reduce summer and fall runoff, and reduce baseflow in streams in the Columbia River Basin. Decreased groundwater infiltration could reduce the project's mine and adit inflows, but because baseflow to streams would also decrease, the percentage change to baseflow may remain the same. If mine and adit inflows decreased, discharges to Libby Creek would be less and makeup water requirements would increase. If climate change did not reduce infiltration enough to change mine and adit inflows from those projected without climate change, any increase in winter streamflows due to climate change may moderate the effect of mine inflows during the winter low flow periods, and any decrease in fall flows may magnify the effect of mine inflows during the fall low flow periods. As described in Appendix C, MMC would monitor streamflows at potential impact area sites and benchmark sites (similar to project area sites, but outside the area of potential mine impacts) to evaluate trends due to mining compared to trends due to non-mining effects such as climate change.

3.11.4.4 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

In Alternative 3, mine facilities would be located in alternate locations. MMC would develop an impoundment site north of Poorman Creek for tailings disposal, use a plant site between Libby and Ramsey creeks, and construct two additional adits in the upper Libby Creek drainage. LAD Areas would not be used. All excess mine and adit water not used for mine operations would be treated at the Libby Adit Water Treatment Plant and discharged to Libby Creek. Treated discharge water would be subject to MPDES permitted effluent limits.

The Libby Plant Site would be built with fill material from a large cut on the west side of the plant site. Based on preliminary analysis, the cut and fill materials would balance, and waste rock would not be used in plant site construction. Avoiding the use of waste rock in plant site construction would minimize the potential for stormwater runoff from the plant site to adversely affect the quality of nearby water resources.

The effects on aquatic life and aquatic habitat due to streamflow changes are described in section 3.6, *Aquatic Life and Fisheries*. The indirect effects due to streamflow changes on riparian vegetation are described in section 3.22, *Vegetation*, and on wetland vegetation are described in section 3.23, *Wetlands and Other Waters of the U.S.* Various mitigations of effects on surface water may be used and are described in sections 2.5.4.3.2, 3.10.4.3.3, or 3.11.4.

3.11.4.4.1 Evaluation and Construction Phases (Years 1 through 5)

The effect on west side streams during the Evaluation and Construction Phases during low flow periods would be small. A decrease of 0.01 cfs (2 percent reduction of the estimated $7Q_{10}$ flow) at EFRC-200 during the Evaluation Phase is predicted. Estimated changes in lake levels and lake surface area would be below what can be accurately calculated. In east side streams, predicted changes during the Evaluation Phase are small decreases (0.02 cfs) between the CMW boundary and the Libby Adit in Libby Creek. The current adit dewatering has likely resulted in a reduction in Libby Creek baseflow, but the effect is not detected because either the reduction is very small and/or there are insufficient baseline data (before the adit was constructed) for comparison to current conditions. Below the Water Treatment Plant at the Libby Adit, predicted discharges of up to 263 gpm would increase flow at LB-300 in Libby Creek by 12 percent of the estimated $7Q_2$ flow and 19 percent of the estimated baseflow. A decrease of 0.01 cfs (2 percent reduction of the estimated $7Q_{10}$ flow) at the CMW boundary at Rock Lake is also predicted. The remainder of this section discusses flow changes during the Construction Phase (Table 108).

Streamflow—West Side Streams

Low Flow

The effect on west side streams during the Construction Phase during low flow periods would be small (up to a loss of 3 percent at EFRC-200), but slightly greater than the Evaluation Phase (Table 108). The effects on aquatic life sites RC-3 and EFBR-2 in the Evaluation and Construction Phases were not estimated, but would be smaller than shown for the Operations Phase (Table 109).

Streamflow—East Side Streams

Low Flow

Low flow in Ramsey, Poorman, and Little Cherry creeks would not be affected during the Evaluation Phase. The effect during the Construction Phase on low flow in Ramsey, Poorman, and Little Cherry creeks would be small (-1 to +3 percent). If baseflow changes in Ramsey Creek adversely affected a senior water right on Ramsey Creek during any mining phase, MMC would develop a plan during final design to convey treated water from the Water Treatment Plant to a location upstream of the right's point of diversion. Discharge to Ramsey Creek would equal MMC's Ramsey Creek baseflow changes whenever the flow at RA-300 was less than 1 cfs. Baseflow in Libby Creek at LB-100 (near the CMW boundary) is predicted not to change during the Evaluation Phase, and is predicted to decrease by up to 9 percent during the Construction Phase. Flow in Libby Creek at and below LB-300 would increase due to discharges from the Water Treatment Plant, which would reach a maximum of 1.11 cfs during the Construction Phase. At LB-300, flow would increase by 0.96 cfs, which would be a 79 percent increase above the estimated baseflow (Table 108). At LB-2000, the increase in $7Q_{10}$ flow is estimated to be 0.67 cfs, a 7 percent increase. The low flow in Bear Creek would not be affected. The effects on aquatic life site LB-2 for the Evaluation and Construction Phases were not estimated, but would be smaller than shown for the Operations Phase (Table 109).

Table 108. Estimated Changes during $7Q_2$ and $7Q_{10}$ Flows, Construction Phase, Alternative 3.

Activity	East Fork Rock Creek EFRC-200†	Rock Creek RC-2000	East Fork Bull River EFBR-500	Ramsey Creek RA-600	Poorman Creek PM-1200	Little Cherry Creek LC-800	Libby Creek LB-300†	Libby Creek LB-2000

†Modeled baseflow values used rather than estimated $7Q_{10}$ flow for EFRC-200 and LB-300 (see section 3.8.3).
Effects shown do not include mitigation measures such as grouting during operations or maintaining barriers in the mine void, or using multiple plugs in the adits during closure. Such mitigation would be evaluated after additional data were collected during the Evaluation Phase. Effects shown do include discharges to Libby Creek and (but not Ramsey Creek) during all phases to avoid adversely affecting senior water rights.
cfs = cubic feet per second; < = less than.
Note: Values shown for modeled baseflow change include 2 years of mining.
Groundwater models were used to predict effects from mine dewatering and the pumpback wells. With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

The primary long-term source of water in the perennial reaches of the four tributaries in the impoundment site is one or more springs located within the footprint of the tailings impoundment. After the springs were filled during the Construction Phase, flow in the perennial reaches downgradient of the impoundment would likely be reduced, at least during baseflow conditions. Perennial flow would change to intermittent or ephemeral flows in some segments.

Table 109. Predicted Changes in Baseflows and Wetted Perimeters at LB-2, RC-3 and EFBR-2 during Operations and Post-Closure, All Mine Alternatives.

Site and Description	LB-2 (Libby Creek above Little Cherry Creek)	RC-3 (East Fork Rock Creek above Confluence with West Fork Rock Creek)	EFBR-2 (East Fork Bull River at Confluence with Isabella Creek)
Existing Conditions and No Action Alternative			
Estimated $7Q_{10}$ Flow (cfs)	8.62	5.70	2.93
Estimated Wetted Perimeter at $7Q_{10}$ Flow (ft^2)	7.38	26.62	1.31
During Operations (Year 22)			
Effect on $7Q_{10}$ Flow (cfs)	+0.82	-0.06	-0.07
% Change in $7Q_{10}$ Flow (cfs)	+10%	-1%	-2%
Effect on Wetted Perimeter (ft^2)	+2.54	-0.28	-0.09
% Change in Wetted Perimeter	+34%	-1%	-7%
During Post-Closure (Year 38)			
Effect on Flow (cfs)	0.00	-0.51	-0.31
% Change in $7Q_{10}$ Flow (cfs)	0%	-9%	-11
Effect on Wetted Perimeter (ft^2)	0.00	-2.52	-0.35
% Change in Wetted Perimeter	0%	-9%	-26%

Effects shown do not include mitigation measures such as grouting during operations or maintaining barriers in the mine void, or using multiple plugs in the adits during closure. Such mitigation would be evaluated after additional data were collected during the Evaluation Phase. Effects shown do include discharges to Libby Creek during all phases to avoid adversely affecting senior water rights.
Source: ERO 2012a.

The current locations and periods of intermittent and ephemeral flow are expected to be similar after construction of the impoundment, but the magnitude of flow would be reduced due to significant reductions in drainage area from the tailings impoundment. The four tributaries have a low capacity to convey water to Libby Creek, and their combined flow of up to 0.7 cfs is much less than the flow of Libby Creek near the impoundment site. The effects on Libby Creek would minor during high flow conditions and negligible or nonexistent for the majority of the year. Appendix L discusses the effects of changes to the four tributaries and Libby Creek due to the tailings impoundment in greater detail.

Peak and Average Annual Flow

During the Construction Phase, less than a 1 percent increase in peak flow from timber clearing for the mine facilities is estimated in all east side streams. All transmission line alternatives combined with Alternative 3 would have estimated increases in peak flow of less than 10 percent. The Poorman Tailings Impoundment would be located in the watersheds of four small drainage channels. This alternative would not require the diversion of Little Cherry Creek or Poorman Creek. Any flow within the watershed above the impoundment would be routed to Poorman Creek or Little Cherry Creek. Water from above the Poorman Tailings Impoundment and Plant

Access Road would be diverted either toward Poorman Creek or Little Cherry Creek, increasing the watershed of both creeks by about 3 percent (ERO Resources Corp. 2010a). ERO Resources' analysis indicated the watershed above the impoundment and access road was 230 acres; NewFields analysis (NewFields 2014b) indicated the area was 270 acres. The difference in effect would be negligible. Average annual flow in both creeks would increase by about 3 percent. Discharges of mine and adit inflows would slightly increase peak flow (less than 1 percent) and average annual flow (about 5 percent) at LB-300. The percent increase in average annual flow below LB-300 would be less as flow increases downstream.

Rock Lake and Rock Creek Meadows

Groundwater discharge into Rock Lake would decrease beginning in the Evaluation Phase and continuing through the Construction Phase. The 3D model predicted very small decreases during the Evaluation (3 acre-feet per year) and Construction Phases (9 acre-feet per year). The effect on the estimated lake volume of 1,302 acre-feet would be negligible. The effect on lake volume, lake level, and surface area during the 2-month late summer/early fall period would be very small, less than can be calculated accurately (Table 114).

The 3D model predicted a decrease of 0.01 cfs in East Fork Rock Creek where it enters Rock Creek Meadows. Observations made during an agency field review in a very dry period (September 2007) indicated that a high water table supported the wetlands. Baseflow in East Fork Rock Creek where it enters Rock Creek Meadows was estimated at 2 cfs. A reduction of 0.01 cfs from an estimated baseflow of 2 cfs in the East Fork Rock Creek at the Meadows would result in a less than 1 percent flow reduction. As discussed in Section 3.11.4.4.2, *Operations Phase,* other sources of water to the Meadows would not be affected by mining. The watershed area for Rock Creek Meadows is about 1,070 acres for the East Fork Rock Creek and 2,970 acres for the other tributaries to Rock Creek Meadows that would not be affected by mining. Based on watershed size and the fact that watershed characteristics are similar to the East Fork Rock Creek watershed, the surface inflow to Rock Creek Meadows from the other tributaries is likely to be about three times greater than that from the East Fork Rock Creek. The hydrology support for the wetland vegetation in Rock Creek Meadows is not expected to be affected.

Stream and Floodplain Crossings

Alternative 3 would require one new road crossing across a major and minor stream (Table 107). The Seepage Collection Pond and infiltration gallery for Libby Creek appropriations would affect 9 acres of the designated 100-year floodplain of Libby Creek. During final design, MMC would avoid or minimize, to the extent practicable, locating facilities, such as the Seepage Collection Pond, in a floodplain. The agencies' monitoring and mitigation plans include the construction of some minor facilities in the Libby Creek floodplain, such as an infiltration gallery for makeup water in Libby Creek, and streamflow measurement devices. No alternative exists to avoid locating these facilities in the Libby Creek floodplain. If locating mine facilities in a floodplain could not be avoided during final design, MMC would submit a floodplain permit application to the DNRC that provides details on the obstruction or use of a floodway/floodplain before construction. DNRC's permit issuance is based on the danger to life and property downstream, availability of alternate locations, possible mitigation to reduce the danger, and the permanence of the obstruction or use (76-5-405, MCA).

3.11.4.4.2 Operations Phase (Years 6 through 25)

Streamflow—West Side Streams

The effect on west side streams during the Operations Phase during low flow periods without mitigation would be a reduction of 0.06 to 0.07 cfs in all west side streams (Table 110). The reduction in low flow would be most pronounced in the East Fork Rock Creek at the CMW boundary (EFRC-200). The 3D model predicted that with MMC's modeled mitigation, the reduction would be 0.05 cfs at EFRC-200, or 0.01 cfs less than shown in Table 110. The flow reduction at EFRC-200 would be 21 percent of the baseflow without mitigation and 17 percent with MMC's modeled mitigation. The effects on aquatic life sites RC-3 and EFBR-2 during Operations (Year 22) and Post-Closure (Year 38) are provided in Table 109. During Operations, the wetted perimeter at RC-3 would be reduced by 1 percent and at EFBR-2 by 7 percent.

Streamflow—East Side Streams

Low Flow

During the Operations Phase, low flow in Libby Creek above LB-300 and its downstream tributaries would be reduced by mine activities. The predicted reductions of the estimated $7Q_{10}$ flow in lower Poorman Creek (PM-1200), without mitigation, would be 12 percent and 19 percent in Little Cherry Creek (LC-800) (Table 110). The *Groundwater Hydrology* section discusses the geology of the impoundment sites. A low permeability bedrock ridge separates groundwater flow between the watershed of Little Cherry Creek and those of Drainages 5 and 10 in the Poorman Impoundment Site. NewFields (2014a) concluded that the bedrock ridge would limit drawdown in the Little Cherry Creek watershed, but drawdown could still extend between watersheds unless the bedrock ridge provided a complete barrier to cross-boundary groundwater flow. Additional subsurface data from this area would be collected during the final design process of the Poorman Impoundment to assess the separation of groundwater flow between the Little Cherry Creek and Poorman Impoundment Site watersheds and the 3D model would be rerun with the new data to evaluate the site conditions.

The 3D model predicted that with mitigation, reductions at RA-600 and PM-1200 would be 0.01 cfs less than shown in Table 110. Low flow in Bear Creek would not be affected. If MMC's Ramsey Creek water appropriation adversely affected a senior water right on Ramsey Creek during any mining phase, MMC would develop a plan during final design to convey treated water from the Water Treatment Plant to a location upstream of the right's point of diversion. Discharge to Ramsey Creek would equal MMC's Ramsey Creek appropriation whenever the flow at RA-300 was less than 1 cfs.

At LB-100 in upper Libby Creek, baseflow is predicted to decrease by up to 22 percent during the Operations Phase. Because of Water Treatment Plant discharges, flow is estimated to increase by 138 percent of the modeled baseflow at LB-300 and by 39 percent of the estimated $7Q_2$ flow. At LB-2000 and aquatic site LB-2, the estimated $7Q_{10}$ flow would increase by 9 percent and $7Q_2$ flow increase by 6 percent. The wetted perimeter at LB-2 would increase by an estimated 34 percent. Low flow in the four unnamed drainages at the impoundment area would be substantially reduced because the watershed would be 87 percent smaller and the pumpback well system would intercept all groundwater that currently flows into the drainages. The agencies' mitigation plans (section 2.5.7 in Chapter 2) describes mitigation that would replace the functions of the channels directly or indirectly affected by the Poorman Tailings Impoundment.

†Modeled baseflow values used rather than estimated $7Q_{10}$ flow for EFRC-200 and LB-300 (see section 3.8.3).
cfs = cubic feet per second; < = less than.
Effects shown do not include mitigation measures such as grouting during operations or maintaining barriers in the mine void, or using multiple plugs in the adits during closure. Such mitigation would be evaluated after additional data were collected during the Evaluation Phase. Effects shown do include discharges to Libby Creek and possibly Ramsey Creek during all phases to avoid adversely affecting senior water rights.
Groundwater models were used to predict effects from mine dewatering and the pumpback wells. With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

Peak and Average Annual Flow

Due to Water Treatment Plant discharges, peak flow would increase slightly (less than 1 percent) and average annual flow by about 5 percent at LB-300, with a smaller percent increase down to LB-2000. Peak flow and average annual flow at and downstream of LB-2000 in Alternative 3 during the Operations Phase would be less than during the Construction Phase due to all of MMC's appropriations, primarily of up to 2.5 cfs during April through July.

Water from above the Poorman Tailings Impoundment and Plant Access Road would continue to be diverted either toward Poorman Creek or Little Cherry Creek, increasing the watershed and average annual flow of both creeks by about 3 percent (ERO Resources Corp. 2010a). The watersheds of the drainages in the Poorman Impoundment Site (Drainages 5 and 10) would be reduced by about 85 percent during Operations. Flow in Drainages 5 and 10, which are currently perennial in upper segments and intermittent in lower segments, would rarely occur during Operations. Flow reduction in the other two channels would be similar.

Rock Lake and Rock Creek Meadows

The 3D model predicted, for an average precipitation year, a decrease of 47 acre-feet per year of groundwater flowing into Rock Lake without mitigation (36 acre-feet with mitigation). The effect on the estimated lake volume of 1,302 acre-feet would be negligible. The effect on lake volume, levels and surface area during the 2-month late summer/early fall period would be very small, less than can be calculated accurately (Table 114). The 3D model predicted a decrease of 0.06 cfs in East Fork Rock Creek where it enters Rock Creek Meadows. It is uncertain whether the effect of mine inflows on Rock Lake during the late summer/early fall period would be greater or less during a multi-year dry or multi-year wet period because these scenarios have not been modeled. The watershed of Rock Lake receives a large amount of precipitation, primarily during the winter and spring, and during a rainy period in late fall. There is enough water even in a very dry year to refill the lake many times during both the snowmelt runoff period and the fall rainy period after drawdown periods when outflows exceed inflows. The water level in Rock Lake would "reset" to full capacity each spring and each fall even during a very dry period (ERO Resources Corp. 2012c).

The groundwater level at the Meadows or other surface flows to Rock Creek Meadows would not be reduced because Rock Creek Meadows and the tributaries that flow into Rock Creek Meadows are outside of the model-predicted drawdown due to mine inflows. MMC completed an annual average water balance for Rock Creek Meadows (MMC 2012f), but did not evaluate the water balance during low flow periods. Observations made during an agency field review in a very dry period (September 2007) indicated that a high water table supported the wetlands. Baseflow in East Fork Rock Creek where it enters Rock Creek Meadows was estimated at 2 cfs. A reduction of 0.06 cfs from an estimated baseflow of 2 cfs in the East Fork Rock Creek at the Meadows would result in a 3 percent flow reduction, and the other sources of water to the Meadows would not be affected by mining. As discussed previously, the surface inflow from the other tributaries that flow directly into the Meadows is likely to be about three times greater than that from the East Fork Rock Creek. The hydrology support for the wetland vegetation in Rock Creek Meadows is not expected to be affected.

3.11.4.4.3 Closure Phase (Years 26 to 30)

Streamflow—West Side Streams

The effect on west side streams would be greater in the Closure Phase than in the Operations Phase. Table 111 provides the unmitigated effects. Low flow would be 0.01 to 0.03 cfs greater than shown in Table 111 with mitigation. The agencies' proposed mitigation and its effectiveness are discussed in section 3.10.4.3.6*, Effectiveness of Agencies' Proposed Monitoring and Mitigation*.

Streamflow—East Side Streams

Low Flow

Libby, Ramsey, Poorman, and Little Cherry Creeks. The following discussion is based the results of the 3D model that did not consider multiple adit plugging for water rights mitigation at Closure. The effects during the Closure Phase without MMC's modeled mitigation or multiple adit plugs would be less than in the Operations Phase (Table 111). Low flow would be 0 to 0.01 cfs greater than shown in Table 111 with MMC's modeled mitigation.

To mitigate effects on senior water rights on Libby Creek and Ramsey creeks, MMC would install plugs at the base of each adit soon after mining operations ceased. Reductions in streamflow due to adit inflows would continue in Libby Creek above LB-300 in Libby Creek, and in Ramsey Creek above RA-300 whenever flow at RA-300 was less than 1 cfs. At LB-100 in upper Libby Creek, baseflow would decrease by up to 19 percent during the Closure Phase. Streamflow reductions would continue and would cease within an estimated one to two decades after all initial adit plugs were in place. The effect would be reduced to a few years if MMC used water diverted from Libby Creek during high flows to fill the adits during the Closure Phase. Below these locations, discharges to mitigate senior water rights would increase flow.

The effect on flow in Little Cherry Creek would be similar to the Operations Phase (Table 111). The role of a bedrock ridge was discussed under the Operations Phase effects.

Peak and Average Annual Flow

The effect during the Closure Phase on peak flow in all east side streams would be small. Due to Water Treatment Plant discharges, peak flow would increase slightly (less than 1 percent) and average annual flow would increase by about 5 percent at LB-300 and by a smaller percent below LB-300 down to LB-2000. MMC's water appropriations, particularly those during April through July if they continued throughout the Closure Phase, would slightly reduce peak and annual flows in Libby Creek at and downstream of LB-2000. Water from above the Poorman Tailings Impoundment and Plant Access Road would continue to be diverted either toward Poorman Creek or Little Cherry Creek, increasing the watershed and average annual flow of both creeks by about 3 percent (ERO Resources Corp. 2010a).

†Modeled baseflow values used rather than estimated $7Q_{10}$ flow for EFRC-200 and LB-300 (see section 3.8.3).
Effects shown do not include mitigation measures such as grouting during operations or maintaining barriers in the mine void, or using multiple plugs in the adits during closure. Such mitigation would be evaluated after additional data were collected during the Evaluation Phase. Effects shown include discharges to Libby Creek (but not Ramsey Creek) during all phases to avoid adversely affecting senior water rights.
Groundwater models were used to predict effects from mine dewatering and the pumpback wells. With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

Rock Lake and Rock Creek Meadows

The effect on Rock Lake would be slightly greater than described in the Operations Phase. The decrease in the flow in East Fork Rock Creek where it enters Rock Creek Meadows would be slightly greater than described in the Operations Phase. Baseflow in East Fork Rock Creek where it enters Rock Creek Meadows was estimated at 2 cfs. A reduction of 0.18 cfs from an estimated baseflow of 2 cfs in the East Fork Rock Creek at the Meadows would result in a 9 percent flow reduction, and the other sources of water to the Meadows would not be affected by mining. As discussed previously, the surface inflow from the other tributaries that flow directly into the Meadows is likely to be about three times greater than that from the East Fork Rock Creek. The hydrology support for the wetland vegetation in Rock Creek Meadows is not expected to be affected.

3.11.4.4.4 Post-Closure Phase (Years 31+)

The Post-Closure Phase would begin after all active reclamation activities were completed. The mine void and adits would continue to fill with water and groundwater levels would continue to decline. After reaching a maximum drawdown and maximum reductions in baseflow in the Rock Creek and East Fork Bull River drainages early in the Post-Closure Phase, the 3D model predicted groundwater levels would begin to recover and would reach equilibrium or steady state in 1,172 years without MMC's modeled mitigation to 1,322 years with MMC's modeled mitigation. Multiple adit plugs, which are a component of the agencies' mitigation that were not simulated in the model, would also increase the time to reach steady state conditions over the mine void because adit inflows would not fill the void. The actual time to recover to steady state would be re-evaluated using the 3D model after additional data were collected during the Evaluation Phase. Once the potentiometric surface stabilized, without MMC's modeled mitigation, groundwater flow to Rock Lake and the baseflow component of streamflow at some stream locations would be reduced.

Streamflow—West Side Streams

The effect on west side streams would be greater than during the Operations and Closure Phases. In Rock Creek and the East Fork Rock Creek, without MMC's modeled mitigation, streamflow is predicted to decrease by a maximum 0.29 cfs at the CMW boundary (EFRC-200) and by 0.65 cfs at the mouth of Rock Creek (RC-2000) (Table 112). The reduction would consist of the entire baseflow at EFRC-200 and 7 percent of the estimated $7Q_{10}$ flow at RC-2000. Rock Creek at the mouth is often dry during low flow periods and the reduction may not be measurable in the channel. When the channel was dry, the effect would be to reduce subsurface flow. The reduction in flow in the East Fork Bull River at the CMW boundary (EFBR-500) would be 0.4 cfs, or 11 percent of the estimated $7Q_{10}$ flow and 7 percent of the estimated $7Q_2$ flow. For the Bull River at the mouth, streamflow is predicted to decrease by a maximum of 0.39 cfs without mitigation, or 1 percent of the estimated baseflow of 40 cfs (Geomatrix 2012).

With mitigation, streamflow is predicted by the 3D model to decrease by 0.17 cfs at EFRC-200 (a 59 percent decrease in baseflow), by 0.15 cfs at RC-2000 (a 2 percent decrease in the estimated $7Q_{10}$ flow), and by 0.39 cfs at EFBR-500 (an 11 percent decrease in the estimated $7Q_{10}$ flow and 7 percent of the estimated $7Q_2$ flow).

The unmitigated effects on aquatic life sites RC-3 and EFBR-2 are provided in Table 109. The predicted wetted perimeter decreases are 9 percent for RC-3 and 26 percent for EFBR-2.

As the mine void filled and groundwater levels over the mine and adits reached steady state conditions, the effects on streamflow would decrease (Table 113). Without mitigation, permanent flow reductions of about 10 percent of the baseflow at EFRC-200 and less than 1 percent of the estimated $7Q_{10}$ flow at RC-2000 are predicted to occur. A permanent decrease of 0.01 cfs is predicted at EFBR-500, and a flow increase of 0.05 cfs is predicted at the mouth of the East Fork Bull River. The uncertainty of the location where streamflow would increase in the East Fork Bull

River is discussed in section 3.10.4.3.4, *Post-Closure Phase* in the *Groundwater Hydrology* section.

At EFRC-200, modeled baseflow is estimated to be reduced by 10 percent without MMC's modeled mitigation (Table 113). Without MMC's modeled mitigation, there is the potential for groundwater to permanently flow from the East Fork Rock Creek watershed to the East Fork Bull River watershed via the mine void because of the very high permeability void that would connect the watersheds. With MMC's modeled mitigation, the flow at EFRC-200 is predicted to return to pre-mining conditions and, the loss of water from the mine void to the East Fork Bull River may be minimized. The flow in East Fork Bull River would permanently decrease by 0.02 cfs in the CMW and 0.01 cfs below the CMW boundary (the same as without mitigation), and the flow of the East Fork Bull River at the mouth would decrease by 0.01 cfs. The agencies' proposed mitigation and its effectiveness in minimizing effects on baseflow are discussed in section 3.10.4.3.6, *Effectiveness of Agencies' Proposed Monitoring and Mitigation* in the *Groundwater Hydrology* section.

Streamflow—East Side Streams

Low Flow

The effects on streamflows shown in Table 112 assume the impoundment was reclaimed, the adits were not plugged near the mine void, the pumpback wells at the tailings impoundment were operating at the same rate as during the Closure Phase (0.55 cfs), and the Water Treatment Plant was used to treat discharged water, some of which would be used to avoid adversely affecting senior water rights. When discharge occurred at the Water Treatment Plant, flow would increase by 0.54 cfs at LB-300 (Table 112). Low flow at LB-2000 would not change. As long as the pumpback well system operated, the low flow in Poorman Creek would be reduced by 0.18 cfs. The reduction at PM-1200 would be 12 percent of the estimated $7Q_{10}$ flow and 7 percent of the estimated $7Q_2$ flow. Low flow in Bear Creek would not be affected. The length of time seepage interception and water treatment would be necessary is unknown, and may be decades or more after operations. If seepage interception and water treatment were not necessary at the time when maximum baseflow reductions occurred, streamflow in Poorman Creek would not be affected, and streamflow in Libby Creek above LB-300 would be affected only by baseflow reductions from mine inflows. At LB-100 in upper Libby Creek, baseflow would decrease by up to 12 percent during the Post-Closure Phase. Low flow in Libby, Ramsey and Poorman creeks would return to pre-mining conditions with or without mitigation when groundwater levels reach steady state conditions (Table 113).

†Modeled baseflow values used rather than $7Q_{10}$ flow for EFRC-200 and LB-300 (see section 3.8.3).
§Assumes impoundment was reclaimed and pumpback well system was operating.
Maximum model predicted baseflow reductions occur at Year 38 for the Rock Creek drainage and Year 52 for the East Fork Bull River drainage. Baseflow changes for east slope watersheds in this table are for Year 38.
cfs = cubic feet per second; < = less than.
Effects shown do not include mitigation measures not provided in MMC's 3D model report such as increasing buffer zones or using multiple plugs in the adits during closure. Such mitigation would be evaluated after additional data were collected during the Evaluation Phase. Effects shown do include discharges to Libby Creek (but not Ramsey Creek) during all phases to avoid adversely affecting senior water rights.
Groundwater models were used to predict effects from mine dewatering and the pumpback wells. With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

Table 113. Estimated Changes during $7Q_2$ and $7Q_{10}$ Flows, Steady State Conditions Post-Closure, Alternative 3.

Activity	East Fork Rock Creek EFRC-200[†]	Rock Creek RC-2000	East Fork Bull River EFBR-500	East Fork Bull River at Mouth	Ramsey Creek RA-600	Poorman Creek PM-1200	Little Cherry Creek LC-800	Libby Creek LB-300[†]	Libby Creek LB-2000

All units are cfs except % change; cfs = cubic feet per second; < = less than.
Groundwater models were used to predict effects from mine dewatering and the pumpback wells. With the data currently available, the model results provide a potential range of dewatering and pumping rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

After the surface of the impoundment was reclaimed and runoff was no longer subject to ELGs and applicable water quality standards were met, a channel would be excavated through the tailings and Saddle Dam abutment to route runoff from the site toward a tributary of Little Cherry Creek. The runoff channel would be routed at no greater than 1 percent slope and along an alignment requiring the shallowest depth of tailings to be excavated down to the channel grade. The side slopes would be designed to be stable and would be covered with coarse rock to prevent erosion. The Little Cherry Creek watershed area where runoff would meet the creek would increase by 633 acres, potentially increasing the flow in Little Creek by an estimated 67 percent (ERO Resources Corp. 2010a). At the mouth of Little Cherry Creek, the watershed would be 644 acres larger, a 44 percent increase. The Hortness method overestimates $7Q_2$ and $7Q_{10}$ flow in watersheds containing the reclaimed impoundment, as discussed previously under Alternative 2. Both $7Q_2$ and $7Q_{10}$ flow likely occur during late summer or early fall during periods of little or no precipitation. The amount of baseflow that would flow during these periods toward Little Cherry Creek would be negligible. The agencies anticipate little or no increase in $7Q_2$ and $7Q_{10}$ flow in Little Cherry Creek. Any increased flow would be partially offset by flow reduction due to the pumpback well system as long as it operated. As discussed in the Operations Phase, the pumpback wells may not affect flow in Little Cherry Creek.

Low flow at LB-2 would not be affected (Table 109) because MMC would discharge water to Libby Creek and possibly Ramsey Creek from water stored in the adits to the extent necessary to avoid adversely affecting senior water rights.

Peak and Average Annual Flow

Reductions in peak and annual flow in east side streams would continue in the Post-Closure Phase. Peak and annual flow in Poorman Creek and Ramsey Creek would return to pre-mine conditions after the tailings impoundment was reclaimed, the adits were completed plugged, and the pumpback well system ceased operations. Peak and annual flow in the four unnamed drainages below the Poorman Impoundment would be substantially less than pre-mine conditions because stormwater from the reclaimed impoundment surface would be diverted to Little Cherry Creek, reducing the watershed of Drainage 10 by 66 percent and the watersheds of the other three drainages by 74 percent (ERO Resources Corp. 2010a in Appendix H).

As long as the pumpback well system operated, flow in the four unnamed drainages at the impoundment area would be substantially reduced. After the impoundment was reclaimed and the pumpback ceased operation, flow in the four unnamed drainages at the impoundment area would be substantially reduced from pre-mine conditions, but slightly greater than in the Operations Phase. Compared to pre-mine size, the watershed of Drainage 10 would be 66 percent smaller and the watersheds of the other three drainages would be 74 percent smaller (ERO Resources Corp. 2010a in Appendix H). Peak flows would be reduced by similar percentages. The Hortness method overestimates $7Q_2$ and $7Q_{10}$ flow in watersheds containing reclaimed impoundments as discussed in Alternative 2. Klohn Crippen (2005) estimated a steady state flow from the underdrain system of 50 to 100 gpm for the Little Cherry Creek impoundment and the agencies anticipate conditions at the Poorman Impoundment Site would be similar. Springs outside of the impoundment footprint that were affected by the pumpback wells would likely return to pre-mine conditions and also may contribute baseflow to channels outside of the impoundment.

After the impoundment was reclaimed, surface water runoff that was diverted to Poorman Creek prior to closure would flow toward the reclaimed impoundment. The watershed and average annual flow in Poorman Creek would return to pre-mine conditions. The watershed area of Little Cherry Creek would increase by 644 acres, an increase of 44 percent (ERO Resources Corp. 2010a). It is expected that average annual flow in Little Cherry Creek would increase by a smaller percentage, as the larger watershed would not increase flow during low-flow periods. The larger watershed would increase runoff during storm events. Due to Water Treatment Plant discharges, peak flow would increase slightly (less than 1 percent) and average annual flow would increase by about 5 percent at LB-300 and by less than 5 percent below LB-300 down to Poorman Creek. The effect on average annual flow in Libby Creek between Poorman Creek and Little Cherry Creek would be offset as result of the diversion of runoff to Little Cherry Creek. Other segments of Libby Creek would return to pre-mine conditions after the tailings impoundment was reclaimed, the adits were completed plugged, and the pumpback well system ceased operations.

As part of the final closure plan, MMC would complete a hydraulic and hydrologic (H&H) analysis of the proposed runoff channel during final design, and submit it to the lead agencies and the Corps for approval. The H&H analysis would include a channel stability analysis and a sediment transport assessment. Based on the analysis, modifications to the final channel design would be made and minor modifications to the upper reaches of the tributary of Little Cherry Creek may be needed to minimize effects on channel stability in the tributary of Little Cherry Creek and to avoid allowing water to pond on the surface of the reclaimed tailings. Other drainage alternatives for the surface of the reclaimed tailings impoundment that protect against erosion but also provide aquatic habitat downstream of the impoundment may be developed with agency approval.

Rock Lake

Effects on Rock Lake during the Post-Closure Phase would be a reduction in groundwater flow to the lake and a reduction in water stored in the lake. The effects would depend on the time of year and whether the potential effects were mitigated. The following discussion is based on the results of the 3D model for an average precipitation year and an analysis of the Rock Lake water balance (ERO Resources Corp. 2012c). It is uncertain whether the effect of mine inflows to Rock Lake during the late summer/early fall period would be greater or less during a multi-year dry or multi-year wet period because these scenarios have not been modeled. The watershed of Rock Lake receives a large amount of precipitation, primarily during the winter and spring, and during a rainy period in late fall. There is enough water even in a very dry year to refill the lake many times during both the snowmelt runoff period and the fall rainy period after drawdown periods when outflows exceed inflows. The water level in Rock Lake would "reset" to full capacity each spring and each fall even during a very dry period (ERO Resources Corp. 2012c).

Without MMC's Modeled Mitigation

Without MMC's modeled mitigation, the potentiometric surface surrounding Rock Lake would continue to decline after mining ceased. When the potentiometric surface decreased below the lake surface, the groundwater flow direction would reverse. As a result, water would flow out of the lake toward the mine void, resulting in a loss of lake volume. The model predicted the loss would occur for about 130 years after mining ceased (Geomatrix 2011c).

The estimated reduction in lake volume, surface area and lake level would be greatest 16 years after mining ceased and the adits were plugged, and would gradually decrease after that time. During the late summer/early fall period, the volume of the lake would be reduced by a maximum of about 4 percent, the surface area would be reduced by a maximum of about 3 percent, and the lake level would decline by 1.2 feet (Table 114). Littoral vegetation, if present in shallow areas of Rock Lake, may experience drier conditions late in the growing season. During the 7-month winter period, the lake volume would be reduced by an estimated 5 percent, the surface area by 4 percent, and the lake level would decline by about 1.5 feet (Table 115).

Table 114. Estimated Effects on Rock Lake during 2-Month Summer/Fall Period.

Phase	Total Mine Depletions During Period (acre-feet)	Initial Lake Volume (acre-feet)	Ending Lake Volume (acre-feet)	Volume Reduction (%)	Change in Lake Level (feet)	Change in Surface Area (acres)	Surface Area Reduction (%)
Construction (without mitigation)	1.5	1,302	1,300.5	<0.1	*	*	*
Operations (without mitigation)	7.8	1,302	1,294.2	0.6	*	*	*
Operations (with mitigation)	6.0	1,302	1,296.0	0.5	*	*	*
Post-Closure (maximum reduction, without mitigation)	53.0	1,302	1,249.0	4	-1.2	1.5	3
Post-Closure (maximum reduction, with mitigation)	20.5	1,302	1,281.5	2	-0.5	0.6	1
Post-Closure (steady state, without mitigation)	4.0	1,302	1,298.0	0.3	*	*	*

* Estimates of changes in lake levels and lake surface area would be very small and cannot be accurately calculated.
cfs = cubic feet per second; < = less than.
A groundwater model was used to predict effects from mine dewatering. With the data currently available, the model results provide a potential range of dewatering rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. The 3D groundwater flow model would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.
Source: ERO Resources Corp. 2012c.

At steady state conditions, the model predicted that the potentiometric surface would not recover completely to pre-mining conditions, resulting in less groundwater flow into the lake. Total groundwater inflow to Rock Lake would be permanently reduced by 24 acre-feet per year, about 2 percent of the estimated full lake volume. During the late summer/early fall period, Rock Lake would have a volume and surface area reduction estimated to be less than 1 percent (Table 114). The volume, surface area, and level of the lake would not be affected during the 7-month winter period (Table 115). The permanent effect on the lake during the 7-month winter period would be a reduction in groundwater inflow to the lake of about 10 percent, which would result in 10 percent less outflow from the lake into the East Fork Rock Creek.

Without mitigation, the change to Rock Lake may be measurable as a long-term trend during periods when deep bedrock groundwater is the only source of supply to Rock Lake, but a trend may be difficult to observe or measure when the lake was ice-covered. The effects on Rock Lake would occur during these two periods, but the lake would refill each year during snowmelt runoff and during late fall precipitation that resulted in runoff to Rock Lake. An analysis of precipitation

Table 115. Estimated Effects on Rock Lake during 7-Month Winter Period during Maximum Reduction in Potentiometric Surface and at Steady State Post-Closure.

Phase	Total Mine Depletions During Period (acre-feet)	Initial Lake Volume (acre-feet)	Ending Lake Volume (acre-feet)	Volume Reduction (%)	Change in Lake Level (feet)	Change in Surface Area (acres)	Surface Area Reduction (%)
Maximum Effect

within the watershed above Rock Lake that considered possible losses before runoff reaching the lake showed that there is enough water even in a very dry year to refill Rock Lake many times during both the snowmelt runoff period and the fall rainy period (ERO Resources Corp. 2012c).

With MMC's Modeled Mitigation

With MMC's modeled mitigation, the 3D model predicted less of a reduction in the potentiometric surface at Rock Lake. During operations, the effect on Rock Lake would be slightly less with MMC's modeled mitigation than without. The estimated reduction in lake volume, surface area and lake level would be greatest 16 years after mining ceased and the adits were plugged. At that time during the 2-month summer/fall period, the volume of the lake would be reduced by an estimated 2 percent, the surface area would be reduced by an estimated 1 percent, and the lake level would decline by 0.5 foot (Table 115).

At steady state conditions, there would be slightly less baseflow (-0.01 cfs) at EFRC-50 upstream of Rock Lake. The 3D model predicted that low permeability barriers would increase groundwater flow toward the lake by 0.01 cfs. The net result would be no change in the lake volume, lake level or surface area at steady state (Table 115). The agencies' mitigation, leaving barrier pillars with access openings that would be plugged at closure with bulkheads, would be designed, based on hydrologic data collected during mining, to minimize post-mining changes in East Fork Rock Creek and East Fork Bull River streamflow and water quality. The mitigation of increasing the buffer zones near Rock Lake and the Rock Lake Fault, which was not modeled, may eliminate effects on Rock Lake during and after mining.

Rock Creek Meadows

The 3D model-predicted effect on the East Fork Rock Creek where it enters Rock Creek Meadows would be greatest 16 years after mine closure, and is estimated to be 0.43 cfs (Klepfer Mining Service 2012). Observations made during an agency field review in a very dry period (September 2007) indicated a high water table supported the wetlands. Baseflow in East Fork Rock Creek at the Meadows was estimated to be 2 cfs (discussed in section 3.10.3.1.2 in the *Groundwater Hydrology* section). A reduction of 0.43 cfs would be about 20 percent of the estimated baseflow in East Fork Rock Creek. Groundwater levels at Rock Creek Meadows and other tributaries that flow into the East Fork Rock Creek at the Meadows are predicted not to be affected by mining. The hydrology support for the wetland vegetation in Rock Creek Meadows is not expected to be affected.

3.11.4.4.5 Climate Change

The effects of climate change in combination with Alternative 3 would be the same as in combination with Alternative 2.

3.11.4.4.6 Uncertainties Associated with Detecting Streamflow Changes due to Mine Activities

The ability to measure streamflow accurately and precisely depends on a number of factors, reviewed by Harmel *et al*. (2006). Potential errors in streamflow measurement are introduced in the measurement of stream depth, velocity, and channel dimensions. Accuracy varies over the distribution of flows, ranging from a few percent for low flows measured with an accurately calibrated weir, to 10 to 15 percent or more for high flows measured by standard stage-to-discharge techniques and calibrated against periodic wading discharge measurements (Grant *et al.* 2008). In an analysis of effects of forest harvest activities on peak flows and channel morphology in the Pacific Northwest, Grant *et al.* (2008) identified a detection limit for changes in peak flow measurements of about ±10 percent; changes in peak flow that fall in this range are within the error of peak flow measurement and cannot be ascribed as an effect.

Harmel *et al.* (2006) reported measurement error in overall streamflow measurement for a “typical” scenario, a “best case” scenario, and a “worse case” scenario. The best case scenario represented measurement procedures used with a concentrated effort in quality assurance/quality control (QA/QC) unconstrained by financial and personnel resource limitations and in ideal hydrologic conditions. The typical scenario represented measurement procedures conducted with a moderate effort at QA/QC and under typical hydrologic conditions. For a typical scenario, estimated measurement error averaged 10 percent and ranged from 6 percent to 19 percent for a range of conditions. The estimated measurement error was 3 percent for the best case scenario, which included flow measurement under ideal hydrologic conditions, specifically a pre-calibrated flow control structure (stable bed and channel) and a stilling well for stage measurement. Measurement error reported by Harmel *et al.* (2006) is consistent with an earlier evaluation of measurement error by the USGS (Sauer and Meyer 1992). Sauer and Meyer reported most measurements will have standard errors ranging from about 3 percent to 6 percent, with a low of 2 percent under ideal conditions.

A recent improvement in streamflow measurement for streams that are at least a foot deep is the use of acoustic Doppler current profilers to measure streamflow. Under suitable conditions, the advantages are that this method is much faster and no less accurate than mechanical current meters, it allows measurements where mechanical current meters are inappropriate or unreliable, and it measures continuous profiles of water velocity, providing more accurate streamflow measurements (Hirsch and Costa 2004).

The natural variability in streamflow also influences the ability to detect a mining-induced change in streamflow. Based on an analysis of streamflow data from streams with gaging stations located at the periphery of the analysis area on the KNF, Wegner (2007) reported the average variability in low flow values is 20 percent. In stream reaches when and where the only source of water to streams is deep bedrock groundwater, it is expected that flow variability would be less. A sufficient number of streamflow measurements could be collected to determine whether the streamflow that may be affected by mining is statistically different from the streamflow that occurred pre-mining, regardless of variability. Although mining-induced streamflow changes would initially be small and gradually increase, a trend should be observable given adequate streamflow monitoring before mining began, during all mining phases, and after mining ceased.

3.11.4.4.7 Effectiveness of Agencies' Proposed Monitoring and Mitigation

Monitoring

MMC would monitor lake levels in Rock Lake and Lower Libby Lake as one component of a comprehensive plan to monitor project effects. MMC began measuring lake level continuously in Rock Lake in 2009 and the KNF currently is monitoring the lake level in Lower Libby Lake. Continued monitoring of lake levels would be effective for subsequently detecting changes in lake levels due to possible dewatering effects of the project. During periods when runoff from precipitation or snowmelt is supplying water to the lake, it probably would not be possible to measure the effect of the project if the lake level changes are in the predicted range of 1 foot or less. Wanless Lake, 4 miles south of Rock Lake and outside of the area of influence of the Montanore Project, would be used as a benchmark lake and would monitored in the same manner as Rock Lake (Appendix C). The monitoring would be effective in assisting MMC and the agencies in separating natural variability from the effects of the mine on Rock Lake.

Streamflow would also be measured at numerous locations during the various mine phases (see Appendix C) to monitor the effects of mine activities. Some sites would be monitored continuously, while others would be measured every other week, monthly or at quarterly intervals when streams were not frozen. For stream sites measured continuously, after adequate data were collected, stage/discharge relationships, daily flows, and yearly hydrographs would be developed and used to estimate baseflow, average, and peak flows. As discussed in the previous section, there are potential errors in streamflow measurement, particularly in rock-filled mountain streams, and during very low flows, but streamflow measurements would be effective for monitoring the effects of mine activities when the agencies' monitoring plans in Appendix C were implemented. Swamp Creek, which originates at the Wanless Lake outlet, would be used as a reference stream on the west side of the divide and Bear Creek would be used as a reference stream on the east side of the divide. These streams are located outside of the area of influence of Alternative 3, and monitoring would be effective in assisting MMC and the agencies in separating natural variability from the effects of the mine on analysis area streams.

Mitigation

Mitigation of effects on the baseflow of streams within the CMW and to Rock Lake, the effectiveness of the mitigations and the uncertainty associated with each mitigation are discussed in detail in section 3.10.4.3.5, *Groundwater Model Uncertainty* and section 3.10.4.3.6, *Effectiveness of Agencies' Proposed Monitoring and Mitigation* in the *Groundwater Hydrology* section. Mitigations would include:

- Buffers around the Rock Lake Fault and Rock Lake where mining would not occur to reduce the risk of high mine inflows and excessive impacts on surface flows and the level of Rock Lake. Based on the 3D model results, buffers would be highly effective in minimizing effects on surface water.
- Barrier pillars in the mine with bulkheads at access openings, if necessary, to minimize post-mining changes in streamflow in East Fork Rock Creek and East Fork Bull River and eliminate the loss of water from storage in Rock Lake. The 3D model results indicated that the concept of barriers in the mine void would be effective in reducing post-mining impacts on streams and in eliminating the loss of water from storage in Rock Lake. Barrier design would be based on an analysis of hydrologic data collected during mining to assess the need for barriers and to optimize their effectiveness.
- Grouting in the mine to reduce adit and mine inflows, which would reduce changes in baseflow in nearby watersheds. With the planned proper maintenance during the Construction and Operations Phases, grouting would be effective in reducing mine and adit inflows. The uncertainty of the effectiveness of grouting over the long term was considered in the agencies' analysis.
- Placing adit plugs post-mining would be effective for separating the mine void from the adits, which would allow streamflows in the Libby Creek watershed to recover to pre-mining conditions more quickly.

Other activities that would reduce streamflow in Libby Creek (capture of precipitation and evaporation in the impoundment, and operation of the pumpback wells) would be effectively mitigated in Alternatives 3 and 4 by discharges of treated water from the Water Treatment Plant that would be equal to or greater than the flow reductions in Libby Creek. The use of thickened tailings in Alternative 3 would reduce the amount of water stored in the tailings by up to about 1 cfs, and reduce makeup water requirements from Libby Creek. Thickened tailings would be an effective mitigation because it would reduce MMC's appropriation at the Libby Creek infiltration gallery. The mitigation for effects on senior water rights in Libby and Ramsey creeks is discussed in section 2.5.4.3.2, *Water Rights* in Chapter 2 and section 3.12.4.3 under *Water Rights*.

The disturbance area of Alternatives 3 and 4 would be less than Alternative 2, which would effectively minimize peak flow increases in all area streams.

In Alternatives 3 and 4, runoff from the reclaimed tailings impoundment would be directed toward Little Cherry Creek instead of Bear Creek proposed in Alternative 2. As part of the final closure plan, MMC would complete a H&H analysis of the proposed runoff channel during final design that would include a channel stability analysis and a sediment transport assessment. The runoff channel design would effectively minimize effects on Little Cherry Creek. Other effects on streamflow in streams other than Libby Creek, such as Poorman and Little Cherry creeks, would be unavoidable.

The agencies' analysis indicates that various discharges or diversions in all mine alternatives may result in changes in the estimated $7Q_{10}$ flow of greater than 10 percent. Although not analyzed, various discharges or diversions also may change the mean monthly flow by more the 15 percent.

The DEQ would determine whether the changes would be nonsignificant during the MPDES permitting process.

3.11.4.5 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Alternative 4 would be similar to Alternative 3, but modified from MMC's proposed Little Cherry Creek Impoundment Site. All other modifications and mitigations described in Alternative 3, other than those associated with the Poorman Tailings Impoundment Site, would be part of Alternative 4. The amount of seepage collected by the Seepage Collection System, which includes seepage from the tailings impoundment, may be increased by optimizing the location of the Seepage Collection Dam where bedrock outcrops in the Little Cherry Creek drainage. Any tailings seepage not intercepted by the drains beneath the impoundment and dams would likely discharge to the former Little Cherry Creek watershed through the fractured bedrock aquifer. Consequently, siting the Seepage Collection Dam at or below the location where bedrock outcrops in the Little Cherry Creek drainage would increase the likelihood that the seepage would be collected by the dam. In Alternative 4, MMC would conduct additional geotechnical work near the Seepage Collection Dam during final design and site the dam lower in the drainage if technically feasible. Pumpback wells would intercept tailings impoundment seepage not intercepted by the underdrain system before it reached surface water.

Effects on west side streams, Rock Lake, and Ramsey Creek would be the same as those described in Alternative 3 during all phases of the project. Effects on Libby Creek would be slightly greater (3 percent) because the tailings impoundment would be 20 acres larger and would intercept more precipitation. Effects on Poorman, Little Cherry and Bear creeks through the Operations Phase would be the same as Alternative 2 without mitigation; these effects were not quantified. Alternative 4 would require two new road crossings across a perennial stream and one new crossing of a non-perennial stream (Table 107).

During the Construction Phase, less than a 1 percent increase in peak flow from timber clearing for the mine facilities is estimated in all east side streams. All transmission line alternatives combined with Alternative 4 would have estimated increases in peak flow of less than 10 percent.

The agencies' monitoring and mitigation plans include the construction of minor facilities in the Libby Creek floodplain, such as streamflow measurement devices and an infiltration gallery for makeup water in Libby Creek. No alternative exists to avoid locating these facilities in the Libby Creek floodplain and the effect would be the same as Alternative 3.

The effect on the Little Cherry Creek floodplain would be less than that described for Alternative 2. In Alternative 4, a new floodplain would be created along the diverted Little Cherry Creek channel.

After the tailings impoundment surface and dams were reclaimed, the runoff would no longer be subject to ELGs. When it met applicable water quality standards, runoff from the reclaimed tailings impoundment surface would be routed via the permanent Diversion Channel and Drainage 10 to Libby Creek (as compared to Alternative 2, where runoff from the reclaimed tailings impoundment surface would flow toward Bear Creek). After the South Saddle Dam and the south Main Dam abutment were reclaimed, runoff would flow to the Diversion Channel. Consequently, the watershed of Drainage 10 would increase by about 500 acres post-mining, as compared to operational conditions. This additional area may require MMC to complete more channel stabilization work in Drainage 10 due to increased flow, plus follow-up monitoring. Average annual flow in the diverted Little Cherry Creek would be about five times the existing flow in Drainage 10 and about 10 percent less than the current flow of Little Cherry Creek (Appendix H).

Compared with the pre-mining watershed area, the post-mining watershed area contributing water to the former Little Cherry Creek channel would be 85 percent smaller directly below the tailings impoundment and 74 percent smaller at the confluence of former Little Cherry and Libby creeks. The Hortness method overestimates $7Q_2$ and $7Q_{10}$ flow in watersheds containing the reclaimed impoundment, as discussed in Alternative 2. Changes in the watershed areas contributing flow to Bear and Libby Creek would be 5 percent or less. Below Bear Creek, streamflow in Libby Creek would return to pre-mining conditions, less any reduced baseflow which would be less than 1 percent of the estimated $7Q_{10}$ flow at Libby Creek at US 2. Following cessation of the pumpback wells and recovery of groundwater levels, springs and seeps outside of the impoundment footprint that were affected by the pumpback wells would likely return to pre-mine conditions and may contribute to baseflow.

3.11.4.6 Alternative A – No Transmission Line

In Alternative A, the transmission line, substation and loop line for the Montanore Project would not be built. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Possible impacts on streams due to construction, operation, and maintenance of a new transmission line, Sedlak Park Substation, and loop line would not occur.

3.11.4.7 Alternative B – MMC Proposed Transmission Line (North Miller Creek Alternative)

3.11.4.7.1 Construction Phase

Alternative B transmission line would have four perennial stream crossings: the Fisher River, Howard Creek, Libby Creek, and Ramsey Creek. The alignment also would have 16 new crossings over other streams. Five new road crossings over other streams would be required. The transmission line would cross 1.1 miles of floodplains and require 1.6 acres of new roads within a floodplain (Table 116). Eight structures would be located in a floodplain. Construction would be curtailed during heavy rains or high winds to prevent erosion to streams. MMC identified four possible methods of stream crossings: fords, culverts, arches, and bridges. Culverts would be the most commonly used crossing method. Because the construction time of the line would be short, MMC anticipates that no drainage would be provided for the temporary roads and would follow the agencies' guidance if installation of culverts were required. Culvert installations on perennial streams would meet BMP requirements. In all transmission line alternatives, the DEQ would require on-site inspections of perennial stream crossings associated with the 230-kV transmission line to determine the most suitable crossing methods and timing of construction that would minimize impacts on floodplains and streamflow (see Environmental Specifications in Appendix D). During construction, streams may be temporarily dammed or routed around construction activities. Damming the stream would reduce or eliminate flow below the dam for a short period of time. After construction was completed, the bridges and culvert would not affect natural streamflow.

Table 116. Comparison of Stream and Floodplain Crossings Required for Transmission Line Alternatives.

Transmission Line Alternative	Number of Stream Crossings by New Roads		Acres of New Roads within FEMA Designated 100-Year Floodplain	Crossings by Transmission Line		
				Miles of Floodplain	Number of Streams	
	Perennial Stream	Other Stream			Perennial Stream	Other Stream
B	0	5	1.6	1.1	4	16
C-R	0	0	0.2	0.4	5	15
D-R	0	0	0.2	0.3	4	18
E-R	0	1	0.2	0.3	4	19

Source: GIS analysis by ERO Resources Corp. using KNF data.

The proposed Sedlak Park Substation would be south of Sedlak Creek and the loop line would cross the creek. Sedlak Creek has a small drainage area and an undefined floodplain. The Sedlak Park Substation and loop line would not affect streamflow in Sedlak Creek.

During the Construction Phase, a 1 percent or less increase in peak flow from timber clearing for the transmission line is estimated in all east side streams. Based on the ECAC model results (Appendix H), the mine-related water yield increase with the combination of Alternative 2 and Alternative B would reach a measurable level in Ramsey and Poorman creeks, with an estimated peak flow increase in Ramsey Creek of 12 percent.

3.11.4.7.2 Operations Phase

The transmission line and associated road crossing culverts would not affect streamflow during operations.

3.11.4.7.3 Decommissioning Phase

As proposed, culverts would remain after the project was completed. The culverts would not affect natural streamflow.

3.11.4.8 Transmission Line Alternatives C-R, D-R and E-R

3.11.4.8.1 Construction Phase

Five perennial streams would be crossed by the transmission line in Alternative C-R: Fisher River, West Fisher Creek, Miller Creek, Howard Creek, and Libby Creek. Preliminary design indicates all transmission line alternatives except Alternative B would span a bend in the creek; it may be possible to avoid spanning the creek during final design. The effect of the Sedlak Park Substation and loop line in all agency alternatives would be the same as Alternative B. The transmission line would cross an estimated 0.4 mile of floodplains and require 0.2 acre of new roads within a floodplain (Table 116). Two structures would be located in a floodplain. Alternative C-R would require no new road crossings over major or minor streams. Culverts would be installed, if needed, on roads used for maintenance access. Other aspects of stream crossings, such as compliance with the Environmental Specifications in Appendix D, would be the same as Alternative B (section 3.11.4.7, *Alternative B – MMC Proposed Transmission Line (North Miller Creek Alternative)*).

Four perennial streams would be crossed by the transmission line in Alternative D-R: Fisher River, West Fisher Creek, Howard Creek, and Libby Creek. The transmission line would cross an estimated 0.3 mile of floodplains and require 0.2 acre of new roads within a floodplain (Table 116). Two structures would be located in a floodplain. Alternative D-R would require no new road crossings over any stream.

Four perennial streams would be crossed by the transmission line in Alternative E-R: Fisher River, West Fisher Creek, Howard Creek and Libby Creek. The transmission line would cross an estimated 0.3 mile of floodplains and require 0.2 acre of new roads within a floodplain (Table 116). Two structures would be located in a floodplain. The alternative would require no new road crossings over perennial streams, and one new crossing over a non-perennial stream. Road and culvert construction, maintenance and removal, and effects on peak flow would be the same as Alternative C-R.

During final design, MMC would avoid or minimize, to the extent practicable, locating structures and roads in a floodplain. If locating transmission line structures and roads in a floodplain could not be avoided during final design, MMC would submit a flood plain permit application to the DNRC that provides details on the obstruction or use of a floodway/floodplain before construction. DNRC's permit issuance is based on the danger to life and property downstream, availability of alternate locations, possible mitigation to reduce the danger, and the permanence of the obstruction or use (76-5-405, MCA).

In Alternatives C-R, D-R, and E-R, installation of culverts, bridges, or other structures at perennial stream crossings would be specified by the agencies following on-site inspections with DEQ, Forest Service, FWP, landowners, and local conservation districts. Installation of culverts or other structures in a water of the United States would be in accordance with the U.S. Army Corps of Engineers 404 and DEQ 318 permit conditions. Work in streams within the transmission line corridor would be in accordance with MFSA certificate requirements. All culverts would be sized according to Revised Hydraulic Guide (KNF 1990) and Parrett and Johnson (2004). Where new culverts were installed, they would be installed so water velocities or positioning of culverts would not impair fish passage. Stream crossing structures would be able to pass the 100-year flow event without impedance.

Based on the KNF ECAC model results (Appendix H), timber clearing for access roads and the transmission line in Alternatives C-R, D-R, and E-R is not predicted to measurably increase the peak flow of any streams. All transmission line alternatives combined with Mine Alternatives 3 and 4 would have estimated increases in peak flow of less than 10 percent.

3.11.4.8.2 Operations Phase

The transmission line and associated road crossing culverts would not affect streamflow during mine operations.

3.11.4.8.3 Decommissioning Phase

After line installation was completed, access roads would be changed to intermittent stored service. Culverts would be removed by the KNF if determined to be high risk for blockage or failure. Stream banks would be laid back to allow streamflow to pass without scouring or ponding. Transmission line roads would be decommissioned after mine closure and removal of the transmission line. Culverts would be removed and fill areas sloped back and stabilized during road decommissioning.

3.11.4.9 Cumulative Effects

3.11.4.9.1 Rock Creek Project

The Montanore and Rock Creek Projects, assuming they occurred concurrently, would cumulatively reduce flow in the Rock Creek, East Fork Bull River, and Bull River watersheds. No other aspects of the two projects would have cumulative effects on surface water resources. MMC's 3D model simulated the concurrent operation of both mines, based on several assumptions regarding the Rock Creek Mine design. The maximum effects on Rock Creek and the East Fork Bull River would occur after both mines ceased operations (assumed to be operating and closing simultaneously). The effects on low flows at RC-2000 and EFBR-500 are provided in Table 117. Compared to direct effects, cumulative flow reductions would be 0.03 cfs greater in Rock Creek at the mouth and the East Fork Bull River at the mouth, and 0.08 cfs greater at EFBR-500 at the CMW boundary. The cumulative effect at EFBR-500 would be a 13 percent reduction in the estimated $7Q_{10}$ flow and an 8 percent reduction in the estimate $7Q_2$ flow. The cumulative reduction in the wetted perimeter of the stream would be 30 percent at EFBR-2, and 18 percent at RC-3. The 3D model predicted that streamflow in the Libby Creek watershed, and Rock Lake levels would not be affected by the Rock Creek mine.

For the Bull River at the mouth, the cumulative effect would be a maximum flow reduction due to mine inflows of 0.48 cfs, which is a 1 percent decrease in the estimated baseflow of 40 cfs at that location (Geomatrix 2011a). During periods of the year when streamflow is dominated by surface water runoff (snowmelt and storm events), the effects on streamflow of the two mine projects would be negligible.

At the mouth of Rock Creek, the predicted reductions in low flows may not be measurable in the stream because the creek is often dry during baseflow periods (the flow reduction would be to subsurface flow). With mitigation, the cumulative effect on the East Fork Rock Creek and Rock Creek would be the same as discussed under the Montanore alternatives.

As the mine void filled and groundwater levels above the mines and adits reached steady state conditions, the effects on streamflow would decrease. Cumulative effects at steady state conditions were not quantified.

RCR prepared a 3D numerical hydrogeological model of the Rock Creek mine area to assist in defining potential impacts on groundwater and surface water resources (Hydrometrics 2014). For the Rock Creek Mine Supplemental EIS, the predicted cumulative effects were estimated by adding the results from the Montanore and Rock Creek 3D models for the respective periods of greatest groundwater drawdown. RCR's model predicted effects were slightly greater than estimated by MMC's 3D model. Because the two models present results for slightly different scenarios, Table 117 includes results for only one bulk hydraulic conductivity (10^{-6} cm/sec) from the Rock Creek model. The Montanore 3D model was used simulate to both unmitigated and mitigated effects, whereas the Rock Creek model only simulated unmitigated effects.

Table 117. Estimated Cumulative Changes during $7Q_2$ and $7Q_{10}$ Flows, Maximum Baseflow Changes during Post-Closure.

Variable	Rock Creek RC-2000		East Fork Bull River EFBR-500		East Fork Bull River @ Mouth	
	Without Mitigation	With MMC's Modeled Mitigation†	Without Mitigation	With MMC's Modeled Mitigation†	Without Mitigation	With MMC's Modeled Mitigation†
MMC's Model Results						
Modeled baseflow change (cfs)	-0.68	-0.19	-0.48	-0.47	-0.36	-0.37
Estimated $7Q_2$ flow (cfs)	13.53	13.53	5.77	5.77	12.27	12.27
Percent Change in $7Q_2$ Flow	-5%	-1%	-8%	-8%	-3%	-3%
Estimated $7Q_{10}$ flow (cfs)	8.80	8.80	3.71	3.71	7.97	7.97
Percent Change in $7Q_{10}$ Flow	-8%	-2%	-13%	-13%	-5%	-5%
RCR's Model Results						
Modeled baseflow change (cfs)	-1.05	—	—	—	-0.80	—
Estimated $7Q_2$ flow (cfs)	13.53	—	—	—	12.27	—
Percent Change in $7Q_2$ Flow	-8%	—	—	—	-7%	—
Estimated $7Q_{10}$ flow (cfs)	8.80	—	—	—	7.97	—
Percent Change in $7Q_{10}$ Flow	-12%	—	—	—	-10%	—

Groundwater models were used to predict effects from mine dewatering and the pumpback wells. With the data currently available, the model results provide a potential range of dewatering and pumping rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. Both 3D groundwater flow models would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see Section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* for more discussion of model uncertainty.

†These are only for unmitigated conditions for the Rock Creek mine because Rock Creek model did not evaluate effects of mitigation.

3.11.4.9.2 Other Reasonably Foreseeable Actions

Cumulative effects in the analysis area on both the east and west slopes of the Cabinet Mountains include past and current actions that are likely to continue in the future and reasonably foreseeable actions that could affect streamflows, spring flows, and lake levels. Other area mining activities, particularly in-stream suction dredging and placer exploration, have in the past created physical substrate habitat alterations in area streams. Other activities that could affect surface water flows include timber harvesting, land clearing, home construction, road construction, septic field installation, water well drilling, livestock grazing, and stream channel and bank stabilization or restoration projects. These activities could either increase or reduce water sources to streams, springs and lakes; other than the Montanore and Rock Creek Projects, cumulative effects would be minor. The cumulative peak flow increase in the Libby Creek and Fisher Creek watersheds would be less than 10 percent. For annual water yield, the cumulative annual flow increases would mostly be less than 1 percent, with the largest impact being a 4 percent increase. These increases would offset flow decreases predicted to occur due to mine inflows and water diversions (Table H-9, Appendix H). For example, in the Ramsey Creek watershed, the analysis predicted a cumulative increase in flow during baseflow periods of 0.2 cfs for Alternative 3. The maximum flow reduction to Ramsey Creek due to mine inflows would be 0.04 cfs. The effects on aquatic life and aquatic habitat due to streamflow changes are described in Section 3.6, *Aquatic Life and Fisheries.* The indirect effects due to streamflow changes on riparian vegetation are described in Section 3.22, *Vegetation*, and on wetland vegetation are described in Section 3.23, *Wetlands and Other Waters of the U.S.*

The proposed Wayup Mine in upper West Fisher Creek and the Libby Creek Ventures drilling plan adjacent to Upper Libby Creek Road would have negligible cumulative effects on streamflows.

3.11.4.10 Regulatory/Forest Plan Consistency

This section discusses compliance with applicable laws and regulations regarding surface water hydrology, specifically changes in streamflow and floodplains. Section 3.13.4.11, *Regulatory/ Forest Plan Consistency* in the subsequent *Water Quality* section (p. 729) discusses compliance with water quality laws and regulations.

3.11.4.10.1 Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources; comply with applicable state and federal water quality standards including the Clean Water Act; take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations; and reclaim the surface disturbed in operations by taking such measures as preventing or controlling onsite and off-site damage to the environment and forest surface resources.

The reclamation plan in all mine and transmission line alternatives would ensure changes in streamflow would be minimized. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8. In these alternatives, MMC did not propose to implement feasible measures to minimize changes in streamflow and to protect fisheries habitat from changes in streamflow. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would incorporate additional feasible and practicable measures to minimize adverse environmental impacts on National Forest surface resources and to maintain and protect fisheries habitat. The measures would include increasing mining buffer zones, installing multiple adit plugs at closure, grouting, and, if necessary, leaving mine void barriers. Using thickened tailings would reduce MMC's appropriation from the Libby Creek and minimize effects on Libby Creek streamflow. The agencies' alternatives expanded MMC's proposed monitoring plans and would include action levels on mine inflows and changes in surface water flow and lake levels that would trigger corrective measures to be implemented by MMC (see Appendix C).

Alternative 2 would have a disturbance area of 2,582 acres. The disturbance area of Alternative 4, which would have a tailings impoundment at the same location as Alternative 2, would be smaller than Alternative 2 by 658 acres by eliminating the LAD disturbance area and minimizing the disturbance area around the tailings impoundment. The disturbance area of Mine Alternative 3 would be the smallest. The smaller disturbance area of Alternatives 3 and 4 minimize peak flow increases in all area streams. Because the clearing width for Transmission Line Alternative B would be narrower than the agencies' transmission line alternatives, the maximum clearing width for Alternative B would be less than the agencies' alternatives. Clearing associated with the agencies' transmission line alternatives would be minimized through the development and implementation of a Vegetation Removal and Disposition Plan.

In Alternatives 3 and 4, runoff from the reclaimed tailings impoundment would be directed toward Little Cherry Creek instead of Bear Creek proposed in Alternative 2. As part of the final closure plan in Alternatives 3 and 4, MMC would complete a H&H analysis of the proposed runoff channel during final design that would include a channel stability analysis and a sediment transport assessment. The runoff channel would be designed to minimize adverse effects of increased streamflow on Little Cherry Creek. MMC's mitigation plans contained limited measures to protect fisheries habitat from changes in streamflow. The agencies' alternatives would create or secure genetic reserves through bull trout transplanting or habitat restoration; rectify factors that are limiting the potential of streams to support increased production of bull trout; and e eradicate non-native fish species, especially brook trout that are a hybridization threat to bull trout. Through these mitigations, the agencies' alternatives would comply with 36 CFR 228.8 to minimize adverse environmental impact.

3.11.4.10.2 Wilderness Act

All mine alternatives have the potential to indirectly affect wilderness qualities. Mitigation measures identified in Chapter 2 for Alternatives 3 and 4 and monitoring required for Alternatives 3 and 4 (Appendix C) would be implemented to minimize changes in wilderness character. Mitigation measures such as increasing the buffer zones near Rock Lake and the Rock Lake Fault, and the agencies' monitoring coupled with final design criteria submitted for the agencies' approval, would reduce the risk of subsidence and measurable hydrological indirect effects to the surface within the wilderness.

Mitigation measures and monitoring requirements in Alternatives 3 and 4 are reasonable stipulations for protection of the wilderness character and are consistent with the use of the land for mineral development. Alternatives 3 and 4 would be conducted to protect the surface resources in accordance with the general purpose of maintaining the wilderness unimpaired for future use and enjoyment as wilderness and to preserve the wilderness character consistent with the use of the land for mineral development and production in compliance with 36 CFR 228.15 and the Wilderness Act. The agencies' mine and transmission line alternatives would comply with the Wilderness Act. Alternatives 3 and 4 would minimize adverse environmental impacts on surface resources within the wilderness, and thereby comply with the regulations (36 CFR 228, Subpart A) for locatable mineral operations on National Forest System lands.

3.11.4.10.3 Clean Water Act and Montana Water Quality Act

The DEQ will discuss compliance with applicable water quality regulations addressing streamflow including nondegradation rules in the ROD and the Statement of Basis for the MPDES permit renewal. 36 CFR 228.8(h) states that "certification or other approval issued by state agencies or other federal agencies of compliance with laws and regulations relating to mining operations will be accepted as compliance with similar or parallel requirements of these regulations." DEQ's permit decision and associated conditions on the MPDES permit renewal or any other state water quality permit would constitute compliance with Montana water quality requirements and Clean Water Act requirements regarding water quality.

3.11.4.10.4 Kootenai Forest Plan

The agencies conducted a floodplain/wetland analysis on all mine and transmission line alternatives, complying with the KFP standard to conduct a floodplain/wetland analysis. The estimated peak flow increase in all mine and transmission line alternatives and all combined mine and transmission line alternatives would be below the peak flow increase guidelines.

3.11.4.10.5 Executive Order 11988 and Montana Floodplain and Floodway Management Act

Transmission line facilities are not subject to the Montana Floodplain and Floodway Management Act. Based on conceptual designs presented in Chapter 2, all mine and transmission line alternatives would have some facilities located in a FEMA designated floodplain. Mine Alternative 2 would have the least amount of disturbance in a FEMA designated floodplain. Construction of the Seepage Collection Pond and an infiltration gallery for makeup water in Mine Alternative 3 would have 9 acres of construction in a floodplain and Mine Alternative 4 would have 3 acres. During final design, MMC would be required to avoid or minimize, to the extent practicable, locating facilities, such as the Seepage Collection Pond in Alternative 3, in a floodplain. If locating mine facilities in a floodplain could not be avoided, an application for a floodplain permit would be submitted to the DNRC that provides details on the obstruction or use of a floodway floodplain and a permit would be required before construction. DNRC's permit issuance is based on the danger to life and property downstream, availability of alternate locations, possible mitigation to reduce the danger, and the permanence of the obstruction or use (76-5-405, MCA). DNRC's permit decision and associated conditions on the floodplain permit for these facilities would constitute compliance with requirements of Executive Order 11988.

In addition to the facilities described above, the agencies' monitoring and mitigation plans associated with Alternatives 3 and 4 would require the construction of some minor facilities in the Libby Creek floodplain, including an infiltration gallery for makeup water and continuous flow measurement devices in the Libby Creek floodplain. In compliance with Executive Order 11988, the KNF finds that no alternative exists to avoid locating these minor facilities in the Libby Creek floodplain. DNRC's permit decision and associated conditions on the floodplain permit would constitute compliance with requirements of Executive Order 11988.

3.11.4.11 Irreversible and Irretrievable Commitments

During operations, use of mine and adit inflows and any water needed for mine operations would be an irretrievable commitment of resources. Any permanent change in stream or spring flow or lake levels due to mining would be an irretrievable and irreversible commitment of resources. Some water would be used consumptively by the project, reducing the total water yield in the region by that amount. Relative to the total yield of the affected watersheds, the consumptively used volume would be small. The reduction in yield would be an irretrievable commitment of resources.

The tailings impoundment in the Little Cherry Creek watershed in Alternatives 2 and 4 would permanently alter the flow in Little Cherry Creek, Bear Creek (Alternative 2 only), Libby Creek, and two unnamed drainages. Alternative 3 would alter the flow in the Little Cherry Creek, Poorman Creek, Libby Creek, and four unnamed drainages. These flow changes would be an irreversible commitment of surface water resources.

3.11.4.12 Short-Term Uses and Long-Term Productivity

The short-term use of surface water resources in the various alternatives would consist of diverting analysis area streams for mining, and using analysis area streams for discharge of treated water. Changes that may occur that would affect the long-term productivity of surface water resources include:

- Changes in flow in streams and springs that receive some of their water supply from bedrock groundwater, as well as changes in the levels of Rock Lake that may occur due to mine inflows
- Changes to watersheds and floodplains (and the streams and springs within them) that would be permanently covered by the tailings impoundment site
- Changes in streamflow that would occur due to permanent stream diversions around or from the tailings impoundment site

3.11.4.13 Unavoidable Adverse Environmental Effects

The consumptive use of groundwater by the project during operations would unavoidably reduce the total water yield from this portion of the Cabinet Mountains. The anticipated consumptive use is expected to be small relative to the total water yield of this area. Water yield would remain reduced until the project no longer consumptively used water, and then slowly return to the pre-mining yield as the mine void filled, which the 3D model predicted would require 490 years. Water levels overlying the mine are predicted by the model to reach steady state conditions 1,150 to 1,300 years after mining ended. The actual time to recover to steady state may be shorter or longer and would be re-evaluated using the 3D model after additional data were collected during the Evaluation Phase). Without mitigation, such as barrier pillars and bulkheads, water levels over the mine void nearest Rock Lake are predicted to remain about 200 feet below pre-mine conditions. Mitigation would reduce this effect. Mining of the ore body would unavoidably reduce streamflow and deep groundwater inflow to Rock Lake. Without mitigation, a change in deep groundwater inflow to Rock Lake would permanently reduce the volume and level of Rock Lake. With mitigation, the volume and level of Rock Lake would be affected until groundwater levels reached steady state conditions. If deep groundwater was a component of the inflow to St. Paul Lake, mine dewatering would unavoidably reduce this source of water to the lake, and the lake level may lower more quickly during dry years when the only source of water to the lake was bedrock groundwater.

3.12 Water Rights

3.12.1 Regulatory Framework

3.12.1.1 Montana Water Use Act

The Montana Water Use Act requires that any person, agency, or governmental entity intending to acquire new or additional water rights or change an existing water right in the state obtain a beneficial water use permit before commencing to construct a new or additional diversion, withdrawal, impoundment, or distribution works for appropriations of groundwater or surface water.

The Montana Water Rights Bureau, within the Water Resources Division of the DNRC, administers the Water Use Act and assists the Water Court with the adjudication of water rights. An Application for Beneficial Water Use Permit requires proof that there is water physically and legally available at the proposed point of diversion in the amount requested (ARM 36.12.1702 and 36.12.1705). Senior water rights have an earlier priority date and claimants who hold them have a higher priority to divert water from a stream or water body than those with more junior rights. If a senior water user would be adversely affected by a new use, the application must include a mitigation plan with specific conditions that the new water user is willing to accept to eliminate or mitigate potential adverse effects on senior water rights. For example, a new water user may need to divert or pump water only at certain times when adequate water is available for all users or may need to find water from another source to replace water appropriated by the new user.

Dewatering the adits or mine void during mining, or filling of the adits and mine void during the Closure and Post-Closure Phases is not a beneficial use of water and a beneficial water use permit would not be required. Although MMC would not be able to obtain a permit to secure an appropriation to dewater the adits or mine void or fill the mine void, the Water Use Act has a requirement that a person cannot waste water, use water unlawfully, or prevent water from moving to another person having a prior right to use the water. If dewatering the Libby Adit or filling of the mine void resulted in one of these, MMC would need a plan to regulate the controlling works of an appropriation as may be necessary to prevent the wasting or unlawful use of water and to ensure that a person having a prior senior right is not deprived of their lawful use of water (85-2-114(1), MCA).

Changes in an existing water right include a change in the point of diversion, place of use, the purpose of use, or the place of storage. A change in a water right can be made as long as there is no adverse impact on other appropriators. Before a change can be initiated, approval from the DNRC must be obtained. Increasing the amount of water consumed from a stream would be considered a new water right requiring an application for beneficial water use.

3.12.1.2 USDA Forest Service/State of Montana Reserved Water Rights Compact

Additional requirements for obtaining a new water rights permit come from the Forest Service/State of Montana Reserved Water Rights Compact (85-20-1401 Article IV B.1., MCA). The compact was entered into by the State of Montana and the United States of America to settle all claims to federal reserved water rights for National Forest System lands administered by the Forest Service. Article IV.B.1.of the compact provides that there will be sequencing of the permitting process for water appropriations under state law and the permitting for access and use of National Forest System lands in relation to water appropriations to avoid conflict between state and federal permitting. Under the compact, an applicant is required to show proof of federal authorization before the application for a new appropriation of water or a change of appropriation will be considered correct and complete when:

- A state permit is required prior to a new appropriation of water, including groundwater, or a change of appropriation, and
- A federal authorization is required to occupy, use, or traverse National Forest System lands for the purpose of diversion, impoundment, storage, transportation, withdrawal, use, or distribution of water for the appropriation or change of appropriation.

A state permit for a new appropriation will be subject to any terms, conditions, and limitations related to the use of water contained in the approved Plan of Operations. For the Montanore Project, the federal authorization for occupancy and use of National Forest System lands in relation to MMC's water appropriations would be the Forest Service's approved Plan of Operations for the project. Any new state permit(s) for water appropriations by MMC would be subject to the terms, conditions, and limitations in the Plan of Operations relating to the use of water.

3.12.2 Analysis Area and Methods

The water rights analysis area is slightly larger than described in section 3.11.2.1, *Analysis Area* and includes the Libby Creek watershed to the Kootenai River and the Bull River below the confluence of the East Fork Bull River to the confluence with the Clark Fork River. Water rights in streams in the transmission line corridors would not be affected. The impact on groundwater rights from pumping the pumpback wells and from mine inflows was evaluated based on the location of the rights with respect to the 3D-modeled drawdown areas. The impact on a spring right located near MMC's proposed infiltration gallery to divert groundwater in the alluvium of Libby Creek was evaluated based on the possible source of water to the spring. Possible impacts on surface water rights due to changes in streamflow were evaluated by comparing requested water appropriations to measured streamflow in all potentially affected streams.

3.12.3 Affected Environment

Surface water in the analysis area is used for a variety of beneficial uses including domestic water supply, irrigation, mining, stock watering, fish habitat, and wildlife. The DNRC has 38 active water rights on record for surface water within the Libby Creek watershed, including diversions from Bear, Ramsey and Libby creeks, as well as unnamed tributaries to Libby Creek. Most of the surface water permits are for domestic, irrigation, fishery and mining use. The total active surface water rights are for an average use of about 55 cfs, and maximum use of about 81 cfs. The 30 spring rights in the Libby Creek watershed are used for primarily for domestic, irrigation and livestock purposes. The livestock rights are for 30 gallons per day per animal unit. The total for the rights (not including stock rights with only animal unit limits) is a maximum flow of 4.93 cfs, and maximum volume of about 1,726 acre-feet. There are 19 groundwater rights listed within the analysis area. Six of these rights are springs, and the rest are wells; the well depth range is 40 to 235 feet, with all but one well less than 100 feet deep. The total for the groundwater rights is a maximum flow of 1.1 cfs, and maximum volume of about 359 acre-feet.

MMC holds two 1902 surface water rights on Libby Creek, one for mining near the Libby Adit site in Section 15, Township 27N, Range 31W (with a maximum diversion of 44.9 gpm between April 1 and December 19, and maximum volume of 50.97 acre-feet), and one for domestic use in the same section (15 gpm year-round, and a maximum volume of 1.5 acre-feet). MMC also holds a 1989 groundwater right near the Libby Adit site in Section 15, Township 27N, Range 31W (with a total diversion of 40 gpm year-round).

The Forest Service has a year-round 40 cfs instream flow right with a 2007 priority date for a segment of Libby Creek that starts at Bear Creek and goes to above Hoodoo Creek. The use of the right is to provide adequate flows for bull trout to migrate from Libby Creek into Bear Creek and spawn. The Forest Service also has a 1949 right to divert 0.5 cfs for mining during May and June from Libby Creek above the confluence with Howard Creek at the Recreation Gold Panning Area, and a 1925 water right on Libby Creek above Ramsey Creek to divert 25 gpm for commercial purposes.

A senior water right holder owns three 1925 surface water rights on Libby Creek for mining, domestic and stock use, and one 1900 water right on Ramsey Creek for mining use. Each of the water rights for mining are for a maximum diversion rate of 1 cfs and maximum volume of 521.6 acre-feet per year.

In Alternatives 3 and 4, MMC would acquire a parcel along US 2 through which Swamp Creek flows for wetland mitigation (see section 2.5.7.1, *Jurisdictional Wetlands and Other Waters of the U.S.*). The current owner of this parcel has a surface water right to flood irrigate 26 acres of hay meadow between May 1 and October 31, with a maximum diversion rate of 291.72 gpm, and maximum volume of 52 acre-feet per year.

No surface water rights exist on the East Fork Bull River and no groundwater rights are in the East Fork Bull River basin. There are three surface water rights on the Bull River downstream of the East Fork Bull River for domestic and irrigation purposes with a total maximum diversion rate of 0.21 cfs and maximum volume of 37 acre-feet per year. One domestic surface water right for 10 gpm and a shallow groundwater right for 20 gpm are held on Rock Creek about 2 miles downstream of the confluence of West Fork Rock Creek and East Fork Rock Creek.

3.12.4 Environmental Consequences

3.12.4.1 Alternative 1 – No Mine

In this alternative, MMC would not develop the Montanore Project. Any existing exploration-related or baseline collection disturbances by MMC would be reclaimed in accordance with existing laws and permits. Surface water and groundwater rights in the area would not be affected. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands.

3.12.4.2 Alternative 2 – MMC Proposed Mine

For all mine alternatives, MMC would have to acquire new surface water and groundwater appropriations from the DNRC to use water for mining and wetland mitigation purposes. MMC did not apply for beneficial water use permits for Alternative 2. MMC estimated that a permit for

200 to 300 gpm would be adequate for mining purposes. The rate and points of diversion for Alternative 2 would vary slightly from those described in Alternative 3. MMC did not propose to discharge treated water to Libby Creek or Ramsey Creek to prevent adverse effects on senior water rights. Baseflow changes and appropriations by MMC from Libby Creek would adversely affect senior water rights. Baseflow changes also may affect senior water rights in Ramsey Creek.

The spring and groundwater well rights located in or near the analysis area are all located outside of the 3D-model predicted drawdown area for mine inflows. There is a water right for a developed spring located near the confluence of Bear Creek and Libby Creek that may be within the drawdown area for the pumpback wells for the Little Cherry Creek tailings impoundment and possibly within the area of influence of the make-up well near Libby Creek. This water right is 76D 28349 00, a 15 gpm water right for mining with a May 1 to September 30 period of use. The source of water for this spring is unknown. If it is alluvial groundwater in the Libby Creek channel, then the flow of the spring may be reduced due to pumping from the pumpback wells or the make-up well, but would be measurable only during low flow periods in Libby Creek. If the source of water for the spring water right is bedrock rather than alluvial water, then appropriation of water by MMC from the make-up well or pumping from the pumpback wells would not affect the flow of the spring.

3.12.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

3.12.4.3.1 Libby Creek

MMC applied for new surface water and groundwater beneficial water use permits using the project components of Alternative 3 (MMC 2012a). Section 2.5.4.3.2, *Water Rights* in Chapter 2 discusses the three water rights for which MMC submitted applications to the DNRC. The applications include a mitigation plan to avoid adversely affecting senior water rights on the mainstem of Libby Creek during the Operations Phase. The DNRC will determine whether requested uses are permittable during the water rights permitting process. The agencies modified MMC's mitigation plan was submitted to the DNRC.

To mitigate effects on senior water rights during all mine phases, MMC would monitor the flow at LB-2000, and whenever flow was less than 40 cfs at LB-2000, would treat and discharge water from the Water Treatment Plant at a rate equal to its Libby Creek watershed appropriations. The agencies anticipate discharges typically would occur in January through March, and August through December. Make-up water during operations would be diverted from Libby Creek during high flows (discussed in the next paragraph). Similar mitigation would occur during the Closure and Post-Closure Phases using water stored in the adits. The effect of filling the mine void with the adits plugged as proposed by the agencies on Libby Creek streamflow has not been quantified. MMC would update the groundwater model in the final closure plan to predict the effect on Libby Creek streamflow of filling the mine void with the adits plugged. Based on this information, MMC would mitigate any effects to senior water rights, if needed, to avoid adversely affecting senior water rights. The agencies' mitigation required in Alternative 3, discussed in Section 2.5.4.3.2, *Water Rights*, would ensure MMC's appropriations or baseflow changes would not injure senior water rights during adit or mine void filling.

In addition to groundwater interception from pumpback wells, and interception of precipitation at the Poorman Impoundment Site, MMC would divert groundwater from an infiltration gallery near Libby Creek during high flows, estimated to be in April through July. The maximum diversion rate would be 1,260 gpm (2.8 cfs). MMC's water rights applications included an analysis on the legal availability of water for such a diversion. The DNRC will determine the legal availability of water for MMC's requested new rights.

If required by the DNRC, MMC would obtain a beneficial use permit for water use at the isolated wetland mitigation sites. If a beneficial use permit was required and obtained, the permit would be conveyed to the Forest Service at the same time the mitigation sites were conveyed.

3.12.4.3.2 Ramsey Creek

On Ramsey Creek, a senior water right holder has a 1 cfs water right for mining between RA-200 and RA-400. The baseflow is estimated to be about 0.38 cfs in Ramsey Creek at the CMW boundary, and may be about 1 cfs at this right's point of diversion on Ramsey Creek. The maximum predicted baseflow decrease due to mine inflows is 0.04 cfs at the CMW boundary and would be similar at the point of diversion. This reduction would adversely affect this water right whenever flow at the point of diversion was less than 1 cfs. MMC would monitor flow in Ramsey Creek at RA-300, above the point of diversion (see Appendix C, Section C.10). When the 3D model was updated after the Evaluation Phase, MMC would re-evaluate potential effects on Ramsey Creek. If the senior water right on Ramsey Creek would be adversely affected during any mining phase, MMC would develop a plan during final design to convey treated water from the Water Treatment Plant to a location upstream of the right's point of diversion (RA-300). Discharge of treated water to Ramsey Creek would require a new outfall in MMC's MPDES permit.

3.12.4.3.3 Swamp Creek

In Alternatives 3 and 4, MMC would acquire a parcel along Swamp Creek for wetland mitigation and the water right associated with this parcel allows for flood irrigation of 26 acres of hay meadow. Rehabilitation of the site to improve its functions as a wetland would not require a water right. MMC would file for a change of use for this water right to an instream flow right.

3.12.4.3.4 Groundwater Rights in the Libby Creek Watershed

The spring and groundwater well rights located in or near the analysis area are all located outside of the 3D-modeled drawdown areas due to mine inflows and the pumpback wells. Developed spring water right 76D 28349 00, a 15 gpm water right for mining with a May 1 to September 30 period of use, is located near and downstream of MMC's proposed infiltration gallery. MMC would divert water at a rate up to 760 gpm from April through July. Assuming that the source of water for the spring water right is alluvial water associated with Libby Creek, it is not expected that pumping from the infiltration gallery during high streamflow (40 cfs or greater) would affect the ability of the spring water rights owner to divert 15 gpm from the spring. If the source of water for the spring water right is bedrock rather than alluvial water, then appropriation of water by MMC from the infiltration gallery would not affect the flow of the spring.

3.12.4.3.5 East Fork Rock Creek, Rock Creek, East Fork Bull River, and Bull River

Water rights in the East Fork Bull River basin would not be affected because there are no existing water rights in that basin. Water rights in the Bull River downstream of the East Fork Bull River would not be affected because the maximum predicted flow reduction would be less than 1 cfs, and the model-estimated baseflow of the Bull River at the confluence with the Clark Fork River is 40 cfs. The surface water right on Rock Creek for 10 gpm is not expected to be affected by the predicted flow decrease due to mine inflows of between 0.5 and 0.65 cfs of the estimated baseflow, which is between 3 and 7 cfs at the point of diversion. The shallow groundwater right for 20 gpm is outside of the area of expected drawdown due to mine inflows.

3.12.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

MMC did not apply for beneficial water use permits for Alternative 4. The rate and points of diversion for Alternative 4 would vary slightly from those described in Alternative 3. The effects on area surface water rights would be the same as described in Alternative 3 and on groundwater rights would be the same as described in Alternative 2.

3.12.4.5 Transmission Line Alternatives

In the transmission line alternatives, the small flow changes expected to occur as a result of water use for dust control or concrete mixing are not expected to adversely affect area water rights. Similarly, the construction and maintenance of the Sedlak Park Substation and the loop line would not affect water rights.

3.12.4.6 Cumulative Effects

Because any new MMC water right could not injure existing water rights, no water rights would be cumulatively affected.

3.12.4.7 Regulatory/Forest Plan Consistency

Alternative 2 would not comply with the Montana Water Use Act or the Montana Reserved Water Rights Compact. MMC did not propose to discharge treated water to Libby Creek or Ramsey Creek to prevent adverse effects on senior water rights. Baseflow changes and appropriations by MMC from Libby Creek would adversely affect senior water rights.

Alternative 3 and 4 would comply with the Montana Water Use Act and the Montana Reserved Water Rights Compact. In Alternative 3 and 4, mine and adit inflows would not be used beneficially during any mine phase and treatment and discharge of all mine and adit inflows would not require a beneficial use permit. MMC would discharge treated water to Libby Creek and Ramsey Creek, as necessary, to prevent adverse effects on senior water rights. At Closure, MMC would install two or more plugs in each of the three Libby Adits. As long as MMC appropriated or diverted water from Libby Creek whenever flow at LB-2000 was less than 40 cfs, MMC would treat, if necessary to meet MPDES permitted effluent limits, stored adit water and discharge it to Libby Creek at a rate equal to all of MMC's Libby Creek appropriations or diversions occurring at that time. Discharges to Ramsey Creek also would be required if the modeling indicated adit inflows during the Closure Phase would adversely affect the senior water right on Ramsey Creek. Any new water right for water use issued pursuant to Montana law for water use in Alternative 3 and 4 would be consistent with the terms of an approved Plan of Operations. An approved Plan of Operations consistent with Alternative 3 or 4 would contain the stipulation that any water right acquired solely for the purposes of mineral development in an approved Plan of Operations would terminate when the Plan of Operations terminated. Any change in beneficial use or place of use of water authorized under an approved Plan of Operations would cause the authorization for that water use to terminate unless prior written approval from the KNF was obtained.

36 CFR 228.8(h) states that "certification or other approval issued by state agencies or other federal agencies of compliance with laws and regulations relating to mining operations will be accepted as compliance with similar or parallel requirements of these regulations." DNRC's permit decision and associated conditions on any beneficial water use permit would constitute compliance with Montana water use requirements.

3.12.4.8 Irreversible and Irretrievable Commitments

Because the 3D predicted streamflow in the Libby Creek watershed eventually would return to pre-mining conditions, no irreversible or irretrievable commitment of resources would occur.

3.12.4.9 Short-Term Uses and Long-Term Productivity

This section is not applicable to water rights.

3.12.4.10 Unavoidable Adverse Environmental Effects

The issuance of new water rights would not adversely affect other water rights.

3.13 Water Quality

3.13.1 Regulatory Framework

3.13.1.1 Permits and Authorizations Held by MMC

3.13.1.1.1 Board of Health and Environmental Sciences Order No 93-001-WQB

NMC submitted a "Petition for Change in Quality of Ambient Waters" in 1989 to the BHES requesting an increase in the allowable concentration of select constituents in surface water and groundwater above ambient water quality, as required by Montana's 1971 nondegradation statute. NMC submitted supplemental information to support the petition in 1992. In response to NMC's petition, the BHES issued an order in 1992, authorizing degradation and establishing limits in surface water and groundwater in the Libby Creek, Poorman Creek and Ramsey Creek watersheds adjacent to the Montanore Project for discharges from the project (BHES 1992; Appendix A). The Order remains in effect for the operational life of the project and for as long as necessary thereafter. The Order established numeric limits for total dissolved solids, chromium, copper, iron, manganese, and zinc in both surface water and groundwater, nitrate+nitrite in groundwater only, and total inorganic nitrogen (nitrate+nitrite+ammonia) in surface water only (Table 118 and Table 119). Although the Order established a limit for copper of 0.003 mg/L, the chronic aquatic life standard of 0.00285 mg/L would be the limiting concentration.

The Order indicates that land treatment, as then proposed and currently proposed in Alternative 2, would satisfy the requirement in ARM 16.20.631(3) (now ARM 17.30.635(3)) to treat industrial wastes using technology that is the best practicable control technology available. In 1992, the DHES (now DEQ) determined that land treatment would provide adequate secondary treatment of nitrate (80 percent removal) and metals. The Order requires the DEQ to review design criteria and final engineering plans to determine that at least 80 percent removal of nitrogen would be achieved and the total inorganic nitrogen concentration in Libby, Ramsey, or Poorman creeks would not exceed 1 mg/L. The Order states "surface water and groundwater monitoring, including biological monitoring, as determined necessary by the Department [DEQ], will be required to ensure that the allowed levels are not exceeded and that beneficial uses are not impaired." The Order also adopted the modifications developed in Alternative 3, Option C, of the Final EIS (USDA Forest Service *et al.* 1992), addressing surface water and groundwater monitoring, fish tissue analysis, and instream biological monitoring.

3.13.1.1.2 MPDES Permit No MT-0030279

The DEQ issued a MPDES permit to NMC in 1997 for Libby Adit discharge to the local groundwater or Libby Creek. Three outfalls were included in the permit: outfall 001 – percolation pond; outfall 002 – infiltration system of buried pipes; and outfall 003 – pipeline outlet to Libby Creek. Only Outfall 001 has been used since permit issuance. The DEQ renewed the permit in 2006. A minor modification of the MPDES permit in 2008 reflected an owner/operator name change from NMC to MMC. In 2011, MMC applied to the DEQ to renew the existing MPDES permit and requested the inclusion of five new stormwater outfalls under the permit. In 2011, the DEQ determined the renewal application was complete and administratively extended the permit (ARM 17.30.1313(1)) until MMC receives the renewed permit.

Table 118. Surface Water Limits Established by BHES Order for the Montanore Project and Montana Surface Water Quality Standards.

Parameter – Category[1]	BHES Order Limit (mg/L)	Human Health Standard (mg/L)	Aquatic Life Standard[2]	
			Acute (mg/L)	Chronic (mg/L)
Temperature (°F) – H	—	—	1ºF max increase for naturally occurring range of 32º to 66ºF, 67ºF max 0.5ºF max increase for naturally occurring 66.5ºF or greater 2ºF per hour max decrease for naturally occurring temperatures above 55ºF; 2ºF max decrease for naturally occurring range of 32º to 55ºF	
pH (s.u.)	—	6.5 – 8.5	6.5 – 8.5	
Dissolved Oxygen[3] – T	—	—	8.0 (early life) 4.0 (other life stages)	9.5 (7-day, early life) 6.5 (30-day, other life stages)
Total dissolved solids (TDS)	100	—	—	—
Total suspended solids (TSS)	—	—	30	20
Turbidity (NTU) – H A-1 waters (within CMW) B-1 waters (outside CMW)	 — —	 — —	 No increase above ambient 5 NTU maximum increase	
Total nitrogen, as N – H July 1 to September 30 October 1 to June 30	 — —	 — —	 0.275 No excessive amounts	
Total Inorganic Nitrogen (TIN), as N – H	1	—	—	
Nitrate + nitrite, as N – T	See TIN value	10	See total nitrogen standard	
Total phosphorus, as P – H July 1 to September 30 October 1 to June 30	 — —	 — —	 0.025 No excessive amounts	
Ammonia, as N – T	See TIN value	—	Calculated based on stream pH	Calculated based on stream pH and temperature
Aluminum[4] – T	—	—	0.75	0.087

3.13.1.2 Applicable Regulations and Standards

3.13.1.2.1 Federal Requirements

Organic Administration Act

The Organic Administration Act authorizes the Forest Service to regulate the occupancy and use of National Forest System lands. The Forest Service's locatable minerals regulations are promulgated at 36 CFR 228, Subpart A. The regulations apply to operations conducted under the U.S. mining laws as they affect surface resources on National Forest System lands under the jurisdiction of the Secretary of Agriculture. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources. 36 CFR 228.8 also requires that mining operators comply with applicable state and federal water quality standards including the Clean Water Act; comply with applicable Federal and State standards for the disposal and treatment of solid wastes; take all practicable measures to maintain and protect fisheries and wildlife habitat which may be affected by the operations; construct and maintain all roads so as to assure adequate drainage and to minimize or, where practicable, eliminate damage to soil, water, and other resource values; and reclaim the surface disturbed in operations by taking such measures as preventing or controlling onsite and off-site damage to the environment and forest surface resources. 36 CFR 228.8(h) states that "certification or other approval issued by state agencies or other federal agencies of compliance with laws and regulations relating to mining operations will be accepted as compliance with similar or parallel requirements of these regulations."

Clean Water Act

The Federal Water Pollution Control Act (Clean Water Act) is designed to protect and improve the quality of water resources and maintain their beneficial uses. Proposed mining activities on National Forest System lands are subject to compliance with Clean Water Act Sections 401, 402 and 404 as applicable. The DEQ, EPA, and the Corps all have regulatory, compliance and enforcement responsibilities under the Clean Water Act. Pursuant to the Clean Water Act, MMC must obtain a 401 certification from the DEQ for proposed discharges of fill into navigable waters unless the DEQ waives its issuance (see section 1.6.2.1, *Montana Department of Environmental Quality*).

A 401 certification from the Montana DEQ certifies that the operator's proposed discharges of fill permitted under a Section 404 permit are in compliance with all applicable water quality requirements of the Clean Water Act. Unless the 401 certification is waived, the mining operator must give a copy of the 401 certification to the Forest Service before the KNF can authorize the operator to commence any activity that requires a 404 permit.

Effluent guidelines are national standards for wastewater discharges to surface waters and publicly owned treatment works (sometimes called municipal sewage treatment plants). The EPA issues effluent guidelines for categories of existing sources and new sources under the Clean Water Act. For industrial sources, national effluent limitation guidelines (ELGs) have been developed for specific categories of industrial facilities and represent technology-based effluent limits. The Montanore Mine site is in an industrial category that is specifically identified and included in the ELGs at 40 CFR 440, Ore Mining and Dressing Point Source Category, Subpart J – Copper, Lead, Zinc, Gold, Silver, and Molybdenum Ores Subcategory.

The federal ELGs apply to mine drainage and process wastewater that discharge to surface water. Mine drainage is "any water pumped, drained, or siphoned from a mine" (40 CFR 440.132). Process wastewater is "any water which, during manufacturing or processing, comes into direct contact with or results from the production or use of any raw material, intermediate product, finished product, by-product, or waste product" (40 CFR 401.11). In terms of the ELG requirements for copper mines that use froth flotation for milling, tailings water is considered process wastewater. Process wastewater from copper mines that use froth flotation for milling may not be discharged to state surface waters except in areas of net precipitation (where precipitation and surface runoff within the impoundment area exceeds evaporation). Because precipitation and surface runoff within the impoundment area would not consistently exceed evaporation, the impoundment in all alternatives would be designed as a zero-discharge facility. The DEQ is responsible for ensuring compliance with the federal ELGs.

Under USDA Nonpoint Source Water Quality Policy Directive 9500-007, the Forest Service agreed to become a Designated Management Agency for National Forest System lands within all states, including Montana. The Forest Service strategy for control of nonpoint source pollution is to require mining operators to apply appropriate BMPs, evaluate BMP performance and initiate corrective action where objectives are not met. The Forest Service's *National Best Management Practices for Water Quality Management on National Forest System Lands* (USDA Forest Service 2012a) are designed to achieve and document water resource protection on National Forest System lands.

A 2008 MOU between the Forest Service and the DEQ entitled "Fostering Collaboration and Efficiencies to Address Water Quality Impairment on National Forest System Lands in Montana" is a component of the national and Montana Nonpoint Source Program and identifies the process of cooperatively ensuring proper design and implementation of water protection management system on National Forest System lands in Montana.

Kootenai Forest Plan

The 1987 KFP established management areas within the forest with different goals and objectives based on the capabilities of lands within the analysis area (USDA Forest Service 1987a). The KFP contains goals, objectives, and standards related to water quality. The KFP established a goal of meeting water quality standards (KFP II-1 #19). To achieve this goal, forest-wide objectives and standards for water quality require application of practicable mitigation measures, such as those identified in the Soil and Water Conservation Handbook (USDA Forest Service 1988b).

3.13.1.2.2 State Requirements

The DEQ is responsible for administering several water quality statutes, including the Public Water Supply Act and the Montana Water Quality Act. The DEQ also administers several sections of the federal Clean Water Act pursuant to an agreement between the State of Montana and the U.S. Environmental Protection Agency. The State of Montana, through the DEQ, has been delegated authority for administering nonpoint source pollution prevention programs, the National Pollutant Discharge Elimination System program, and water quality standards. The Water Quality Act provides a regulatory framework for protecting, maintaining, and improving the quality of water for beneficial uses. Pursuant to the Water Quality Act, the DEQ has developed water quality classifications and standards, as well as a permit system to control discharges into state waters. Mining operations must comply with Montana's regulations and standards for surface water and groundwater.

MPDES permits are required for discharges of wastewater to state surface water. MPDES permits regulate discharges of wastewater by imposing, when applicable, technology-based effluent limits and state surface water quality standards, which include numeric and narrative requirements, nondegradation criteria, and Total Maximum Daily Loads. Montana Ground Water Pollution Control System permits are required for discharges of wastes to state groundwaters. Discharges to groundwater from mining operations subject to operating permits under the Metal Mine Reclamation Act are not subject to groundwater permit requirements (75-5-401(5), MCA).

Water Quality Standards

The DEQ classifies all surface water in the analysis area as either A-1 (within wilderness areas) or B-1. Water quality standards are nearly identical for A-1 and B-1 waterbodies. An A-1 classification has stricter protection requirements associated with allowable levels of impurities for drinking, culinary, and food-processing purposes, and stricter protection requirements associated with allowable levels of turbidity. The water quality of both A-1 and B-1 waterbodies must be suitable for bathing, swimming, and recreation, aquatic life, wildlife, and agricultural and industrial uses. Surface water in the wilderness is classified as A-1, where stricter allowable changes are defined to maintain the water quality classification.

Montana surface water quality standards for inorganic pollutants applicable to the project are provided in Table 118. The DEQ also has required reporting limits for pollutants. Both Montana's surface water and groundwater rules contain narrative standards (ARM 17.30.620 through 17.30.670 and ARM 17.30.1001 through 17.30.1045). The narrative standards cover a number of parameters, such as alkalinity, chloride, hardness, sediment, sulfate, and total dissolved solids (for surface water), for which sufficient information does not yet exist to develop specific numeric standards. These narrative standards are directly translated to protect beneficial uses from adverse effects, supplementing the existing numeric standards. The narrative standard for nutrients is that state surface waters must be free of substances that will create conditions that produce undesirable aquatic life (ARM 17.30.637). For B-1 streams, short-term narrative standards for total suspended sediment and turbidity may be established for stream-related construction activities.

Effective August 8, 2014, the Board of Environmental Review adopted numeric standards for total phosphorus and total nitrogen for wadeable streams in Montana Ecoregions (DEQ 2014a). Wadeable streams are perennial or intermittent streams in which most of the wetted channel is safely wadeable by a person during baseflow conditions; this includes all streams in the analysis area. The analysis area is in the Northern Rockies Ecoregion; all wadeable streams have a seasonal total phosphorus standard is 0.025 mg/L and a seasonal total nitrogen standard is 0.275 mg/L between July 1 to September 30. The narrative nutrient standard applies during October 1 to June 30. Because the numeric nutrient standards are stringent and may be difficult for MPDES permit holders to meet in the short term, Montana's Legislature adopted a law (75-5-313, MCA) allowing for the achievement of the standards over time via variance procedures found in Circular DEQ-12B (DEQ 2014b). A MPDES permit holder may apply for a general variance for either total phosphorus or total nitrogen, or both. The general variance may be established for a period not to exceed 20 years. MMC's water treatment plant in the agencies' alternatives would have a design capacity greater than 1 million gallons per day. Based on this design capacity, a general variance, if granted to MMC, would allow a variance at the end-of-pipe at the Water Treatment Plant of 10 mg/L for total nitrogen and 1 mg/L for total phosphorus. Montana law also allows for the granting of individual nutrient standards variances based on the particular economic and financial situation of a permittee (75-5-313(1), MCA). Individual nutrient standards variances may be granted on a case-by-case basis because the attainment of the base numeric nutrient standards is precluded due to economic impacts, limits of technology, or both (DEQ 2104b).

The DEQ classifies all groundwater in the analysis area as Class I, which are suitable with little or no treatment for public and private drinking water supplies, culinary, and food preparation purposes, irrigation, drinking water for livestock and wildlife, and commercial and industrial purposes. Montana groundwater quality standards for inorganic pollutants applicable to the project are shown in Table 119.

The DEQ may authorize short-term surface water quality standards for total suspended sediments and turbidity for construction of the powerline, access roads, the tailings impoundment, and other stream crossings (75-5-318, MCA). Any exemption would include conditions that minimize, to the extent practicable, the magnitude of any change in water quality and the length of time during which any change may occur. The authorization also would include site-specific conditions that ensure that the activity is not harmful, detrimental, or injurious to public health and the uses of state waters and that ensure that existing and designated beneficial uses of state water are protected and maintained upon completion of the activity. The DEQ may not authorize short-term narrative standards for activities requiring a discharge permit.

Nondegradation Rules

The Montana Water Quality Act requires the DEQ to protect high quality waters from degradation. The current nondegradation rules were adopted in 1994 in response to amendments to Montana's nondegradation statute in 1993 and apply to any activity that is a new or increased source that may degrade high quality water. These rules do not apply to water quality parameters for which an authorization to degrade was obtained prior to the 1993 amendments to the statute. NMC, MMC's predecessor, obtained an authorization to degrade in 1992 for certain water quality parameters. For those parameters, the limits contained in the authorization to degrade apply. For those parameters not covered by the authorization to degrade, the applicable nonsignificance criteria established by the 1994 rules, and any subsequent amendments, apply (ARM 17.30.715), unless MMC obtained an authorization to degrade under the current statute.

The nondegradation rules (ARM 17.30.715(1)) state that changes in existing surface water quality resulting from the activities that meet the criteria listed below are nonsignificant, and are not required to undergo degradation review:

- Discharges containing carcinogenic parameters, such as arsenic or beryllium, or parameters with a bioconcentration factor greater than 300, such as mercury, at concentrations less than or equal to the concentrations of those parameters in the receiving water;
- Discharges containing toxic parameters, including ammonia, nitrate plus nitrite, nitrite, aluminum, antimony, barium, cadmium, chromium, copper, lead, nickel, selenium, silver, and zinc, which will not cause changes that equal or exceed the trigger values in Circular DEQ-7 (trigger values are used to determine if proposed activities will cause degradation). Whenever the change exceeds the trigger value, the change is not significant if the resulting concentration outside of a mixing zone designated by the DEQ does not exceed 15 percent of the lowest applicable standard;
- Discharges containing harmful parameters, such as iron, turbidity, total nitrogen, and total phosphorus, that do not cause changes outside the mixing zone greater than 10 percent of the applicable standard and where the existing concentration is less than 40 percent of the standard; and
- Discharges causing changes in the quality of water for any parameter for which there are only narrative water quality standards if the changes do not have a measurable effect on any existing or anticipated use or cause measurable changes in aquatic life or ecological integrity.

Notwithstanding compliance with the nonsignificance criteria in ARM 17.30.715(1), the DEQ may determine under ARM 17.30.715(2) that a change in water quality is degradation based on the following criteria: a) cumulative impacts or synergistic effects; b) secondary byproducts of decomposition or chemical transformation; c) substantive information derived from public input; d) changes in flow; e) changes in the loading of parameters; f) new information regarding the effects of a parameter; or g) any other information deemed relevant by the DEQ and that relates to the criteria in ARM 17.30.715 (1). Under ARM 17.30.715(3), the DEQ may determine that a change in water quality is nonsignificant based on information submitted by an applicant that demonstrates conformance with the guidance found in 75-5-301(5)(c), MCA which is: i) potential for harm to human health, a beneficial use, or the environment; ii) strength and quantity of any pollutant; iii) length of time the degradation will occur; and iv) the character of the pollutant so that greater significance is associated with carcinogens and toxins that bioaccumulate or biomagnify and lesser significance is associated with substances that are less harmful or less persistent. Such a determination would be submitted for public comment before making a decision. Under the Montana Water Quality Act, no authorization to degrade may be obtained for outstanding resource waters, such as surface waters within a wilderness.

Total Maximum Daily Loads

Section of the federal Clean Water Act requires states to assess the condition of state waters to determine where water quality is impaired (does not fully support uses identified in the stream classification or does not meet all water quality standards) or threatened (is likely to become impaired in the near future). The result of this review is the compilation of impaired surface waters, which states must submit to the EPA biannually. Section also requires states to prioritize and target water bodies on their list for development of water quality improvement strategies (*i.e.*, TMDLs), and to develop such strategies for impaired and threatened waters. A TMDL is the maximum amount of a pollutant a river, stream or lake can receive and still support all designated uses. Three streams in the analysis area are listed on the most current Montana list of impaired streams (DEQ 2012b). These streams are two segments of Libby Creek, the Fisher River, and Rock Creek.

Libby Creek is separated into two segments on the 2012 list of impaired surface waters. The upper segment is from 1 mile above Howard Creek to the US 2 bridge. This segment is listed as not supporting drinking water and partially supporting its fishery and aquatic life. Agricultural and industrial beneficial uses are fully supported. Contact recreation has not been assessed. Probable causes of impairment listed in 2012 were alteration in stream-side or littoral vegetative covers, mercury, and physical substrate habitat alterations. Probable sources of impairment were impacts from abandoned mine lands and historic placer mining. The lower segment begins at the US 2 bridge and is impaired for sediment and siltation. Both segments may be affected by proposed activities in all mine alternatives. In 2014, the DEQ and the EPA issued TMDLs and a water quality improvement plan for the Kootenai River-Fisher River project area, which includes Libby Creek. The DEQ performed updated assessments on Libby Creek for metals impairment and did not identify metals impairment conditions in Libby Creek in the reassessment (DEQ and Environmental Protection Agency 2014). The impairment causes for this 1 mile section of Libby Creek (mercury) will be removed from the 2014 Water Quality Integrated Report. The remaining impairments for this section, alteration in stream-side or littoral vegetative covers and physical substrate habitat alterations, do not require development of a TMDL (DEQ and Environmental Protection Agency 2014). The DEQ and EPA established a sediment TMDL of 4,234 tons/year average annual load for Libby Creek from the US 2 bridge to the confluence with the Kootenai River. MMC would implement BMPs included in the MPDES permit to meet the sediment wasteload allocation of 24 tons/year developed in the TMDL for the project.

The Fisher River from the Silver Butte/Pleasant Valley junction to the Kootenai River is impaired, with aquatic life support and cold-water fishery uses only partially supported. Probable causes for the Fisher River impairment were listed in 2012 as a high flow regime and high lead concentrations (source unknown), with probable sources of these impairments listed as channelization, grazing, road runoff, road construction, silvicultural activities, and stream bank modification and destabilization. In 2014, the DEQ and EPA issued draft and a water quality improvement plan for the Kootenai River-Fisher River project area, which included the Fisher River. The DEQ performed updated assessments on the Fisher River for metals impairment and did not identify metals impairment conditions in the Fisher River in the reassessment (DEQ and Environmental Protection Agency 2014). The impairment causes for the Fisher River (lead) will be removed from the 2014 Water Quality Integrated Report. The remaining impairment, high flow regime, does not require development of a TMDL (DEQ and Environmental Protection Agency 2014).

Rock Creek is impaired from the headwaters (including Rock Lake and East Fork Rock Creek) to the mouth at the Clark Fork River, with aquatic life support and cold-water fishery uses only partially supported. Probable causes for the Rock Creek impairment were listed in 2012 as other anthropogenic substrate alterations, with probable sources of these impairments listed as silvicultural activities. In 2010, the DEQ issued sediment TMDLs and a framework for water quality restoration for the lower Clark Fork River tributaries, which included Rock Creek. The DEQ concluded Rock Creek's impairment is not a pollutant and does not require a TMDL (DEQ 2010a).

3.13.2 Analysis Area and Methods

3.13.2.1 Analysis Area

The groundwater quality analysis area is the same as groundwater hydrology and is described in section 3.10.2.1, *Analysis Area.* The surface water quality analysis area is the same as surface water hydrology and is described in section 3.11.2.1, *Analysis Area.*

3.13.2.2 Methods

3.13.2.2.1 Baseline Data Collection

NMC began surface water quality data collection in the analysis area in 1988 and MMC has continued data collection to the present time. In addition, the Forest Service has collected water quality data on some analysis area streams since 1960. Details of the surface water baseline data collection through 2009 are provided in the Data Collection section of the *Final Baseline Surface Water Quality Technical Report* (ERO Resources Corp. 2011c). The Forest Service is conducting a long-term air quality study that began in 1991 that includes lake chemistry monitoring of Upper and Lower Libby Lakes (Grenon and Story 2009, McMurray 2013). Gurrieri and Furniss (2004) reported results of chemical analyses at Rock Lake of bulk atmospheric deposition, lake water, surface inflow, and springs collected manually in 1999 at two- to four-week intervals during the ice-free period. Snow samples were collected in June 1999 at Rock Lake. Kline Environmental Research and NewFields (2012) reported water quality field parameters for drainages in the Poorman Impoundment Site, and in headwater tributaries in the mine area.

NMC collected groundwater data from monitoring wells in the Little Cherry Creek and Poorman Tailings Impoundment Sites, LAD Areas, and Libby Adit Site between 1988 and 1995 (Geomatrix 2006c). The sampling frequency varied from one to multiple times per year. Water samples were collected from wells in the Poorman Tailings Impoundment Site between 1988 and 1993 and analyzed for most major cations and anions and total dissolved solids. MMC collected quarterly groundwater quality data from two monitoring wells beginning in 2005, one in the Little Cherry Creek Tailings Impoundment Site (LCTM-8V) and one near the proposed LAD Areas (WDS-1V). MMC also collected monthly groundwater quality data from two monitoring wells at the Libby Adit Site (MW07-01 and MW07-02) beginning in 2007.

3.13.2.2.2 Impact Analysis Methods

Mass Balance Analysis

A mass balance approach was used to predict potential surface water quality changes resulting from mine wastewater discharge. For Alternatives 3 and 4, mass balance calculations were completed for Libby Creek at LB-300 where discharges from the Water Treatment Plant would be made. For Alternative 2, the agencies completed mass balance calculations for three streams near where discharges from the Water Treatment Plant or from the LAD areas would occur: Libby, Poorman, and Ramsey creeks. Locations analyzed on Poorman and Ramsey creeks for the Alternative 2 LAD areas were PM-1200, RA-400 and RA-600 downgradient of the two proposed LAD areas (data used for PM-1200 were collected at PM-1000, and data used for RA-600 were collected at RA-500, RA-550, and RA-600). In all alternatives, mass balance calculations were completed at locations on Libby Creek at LB-1000 and LB-2000, downgradient of the discharges. In the calculations, a representative wastewater quality at an estimated flow rate was mixed with a representative surface water quality at an estimated flow rate to estimate a final surface water concentration. The mass balance calculations presented in Appendix G provide predicted concentrations, after mixing, of total dissolved solids, ammonia, nitrate, total inorganic nitrogen (which was treated in the calculations as the sum of ammonia + nitrate), total nitrogen, total phosphorus, aluminum, antimony, arsenic, barium, beryllium, cadmium, chromium, copper, iron, lead, manganese, mercury, nickel, selenium, silver, and zinc. Data were also collected for thallium, but thallium was not detected in surface water, groundwater, or adit and mine water, and it is not discussed further.

Because the numeric nutrient standards are stringent and may be difficult for MMC to meet in the short term, the agencies' analysis assumed that MMC would receive a general variance from the base nitrogen and phosphorus standards. For total phosphorus, it was assumed for the impact analysis that MMC would obtain a general variance of 1 mg/L. For total nitrogen, it was assumed that MMC would receive a general variance of 10 mg/L. Because nitrate would be the dominant nitrogen form, the analysis assumed that the BHES Order limit of 1 mg/L for TIN would be the applicable limit for nondegradation purposes. The DEQ will complete a nondegradation review and set effluent limits during the MPDES permitting process. The nitrogen and phosphorus limits of 1 mg/L for ambient surface waters could be modified in the MPDES permit issued by DEQ at any time if nuisance algal growth caused by MMC's discharge was observed.

For discharges to groundwater at the LAD Areas and tailings impoundment sites, dissolved metal concentrations were used. For MMC's proposed discharges to LAD Areas, some of which would also reach surface water, dissolved metal concentrations were used for the representative wastewater quality because discharges would flow through unconsolidated materials and reach groundwater before reaching surface water.

Potential changes in groundwater quality were assessed by developing representative wastewater quality that would be discharged to groundwater, such as seepage from the tailings impoundment in all mine alternatives and water applied to the LAD Areas in Alternative 2. The agencies completed mass balance calculations for discharges at the impoundment sites and LAD Areas. Representative wastewater quality at an estimated flow rate was mixed with representative ambient groundwater at an estimated groundwater flux to estimate a final groundwater concentration. The uncertainties associated with the mass balance calculations are discussed in section 3.13.4.5, *Uncertainties Associated with the Water Quality Assessment*. The agencies' approach to developing representative concentrations is discussed in subsequent sections.

Streamflows used for the calculations were estimated $7Q_{10}$ flow less any pre-discharge depletions (see next section), except for LB-300, where the modeled baseflow less any pre-discharge depletion due to mine inflow was used (see section 3.8.3). Discharge rates used in the mass balance calculations are provided in Appendix G.

Stormwater runoff events associated with storms exceeding the 10-year/24-hour storm (the design capacity of the Alternative 2 stormwater retention ponds) were not analyzed. The water quality of both the storm runoff and the storm flows of the receiving streams are unknown. A qualitative analysis of possible changes in stream water quality during storm runoff events was completed. Streamflow would be very high during such an event, with discharges to Poorman and Ramsey creeks likely less than 5 percent of the high flows. Any discharges from stormwater retention ponds would be sampled and regulated.

Surface water quality changes to streams, springs, and lakes due to reduced contributions from deeper bedrock groundwater were evaluated qualitatively. Available data on the relative contribution of direct surface runoff, shallow groundwater, and deeper bedrock groundwater, and the water quality of each source to surface water at specific locations are not adequate for a quantitative analysis.

The following subsections describe the streamflow rates, groundwater flux, receiving and wastewater quality values used in the mass balance calculations.

Streamflow Rates Used in Mass Balance Analyses

The DEQ's standard surface water mixing zone rules (ARM 17.30.516) require the use of the $7Q_{10}$ flow to assess effects of discharges that may affect surface water. The $7Q_{10}$ flow is the lowest 7-day average flow that occurs on average once every 10 years. The USGS (Hortness 2006) developed the method used by the agencies to estimate $7Q_{10}$ flow (Appendix G). The estimated $7Q_{10}$ flow for analysis area monitoring locations is:

- 2.06 cfs (925 gpm) for Ramsey Creek at RA-400
- 2.07 cfs (929 gpm) for Ramsey Creek at RA-600
- 1.55 cfs (696 gpm) for Poorman Creek at PM-1200
- 3.03 cfs (1,361 gpm) for Libby Creek at LB-300
- 8.59 cfs (3,855 gpm) for Libby Creek at LB-1000
- 8.99 cfs (4,035 gpm) for Libby Creek at LB-2000

For LB-300, the flow used in the mass balance analyses was 1.22 cfs, which was the baseflow for LB-300 estimated in the 3D groundwater model. The reason for using the modeled baseflow rather than the estimated $7Q_{10}$ flow at LB-300 is explained in section 3.8.3. This baseflow was the flow estimated by the 3D model for average climate conditions; it is possible that the flow at LB-300 might be lower than 1.22 cfs when climate conditions were drier and/or hotter than average.

For the mass balance analyses, the flow reductions estimated by the 3D model were subtracted from the estimated $7Q_{10}$ flow (or from the modeled baseflow at LB-300), potable water use (9 gpm) was subtracted from the Libby Creek flows, and water diverted from Libby Creek by the impoundment and pumpback wells (up to 247 gpm) was subtracted from the Libby Creek flows in the pumpback well area of influence (at LB-2000 for Alternatives 2 and 4 and LB-1000 and 2000 for Alternative 3). The resulting flows were used in the mass balance calculations.

Groundwater Flux Used in Mass Balance Analyses

Section 3.10.4.2.1, *LAD Areas* provides the agencies' analysis of the maximum possible application rate of wastewater that could occur to the LAD Areas based on guidance documents from the Corps and EPA (Corps 1982; Environmental Protection Agency 2006b) and limitations due to the hydrologic characteristics of subsurface unconsolidated materials. The maximum application rate to the LAD Areas that the agencies estimated would be 130 gpm. The application rate was used in the agencies' analysis of effects for Alternative 2; application rate would vary and would be based on BHES Order limits and MPDES permitted effluent limits. Applied water that was not evapotranspired would percolate to and then mix with groundwater and then flow to adjacent streams. For Alternatives 3 and 4, the agencies assumed that all water treated and released from the Water Treatment Plant to Libby Creek, and, if necessary for water right concerns, to Ramsey Creek, would meet BHES Order limits or applicable nondegradation criteria at the end of a mixing zone in accordance with the MPDES permit.

Tailings seepage was estimated with groundwater modeling conducted of the Little Cherry Creek Impoundment Site for MMC (Klohn Crippen 2005) and independently verified by the lead agencies (USDA Forest Service 2008). Seepage not collected by the underdrain is expected to flow to groundwater at a rate of about 25 gpm and, after the impoundment was reclaimed, slowly decrease to 5 gpm (Klohn Crippen 2005). The agencies used the same estimates for the Poorman Impoundment Site because of the similarity in the geologic conditions and in the proposed underdrain system at both sites. For the mass balance analysis to estimate effects on groundwater quality, the groundwater flux (volume per unit time) beneath the Little Cherry Creek impoundment was estimated to be about 35 gpm (Geomatrix 2007b) and the agencies estimated a groundwater flux of 41 gpm under the Poorman tailings impoundment. Downgradient of the tailings impoundment, such water would be captured by a pumpback well system before reaching surface water and returned to the tailings impoundment.

Receiving Water Quality Used in Mass Balance Analysis

Receiving water quality includes both surface water and groundwater. For the mass balance analyses, estimates of the representative water quality of the streams that would receive wastewater discharges were derived from surface water monitoring data collected from 1988 to 2012 (ERO Resources Corp. 2011c; MMC 2008, 2009b, 2010, 2011b, 2012g, 2013). Representative surface water concentrations are provided in Appendix K-1. For the analyses for the Alternative 2 LAD Areas and the tailings impoundment for all alternatives, estimates of the ambient groundwater quality were derived from groundwater data collected from 2005 to 2009 (MMC 2008, 2009b, 2010). Water quality in a well in the Little Cherry Creek Impoundment Site was used to represent ambient concentrations at both impoundment sites. Representative concentrations for each parameter in groundwater are provided in Appendix K-4.

Representative values were determined after removing data outliers. For water quality parameters with no below detection limit values, the representative value is the median concentration. For parameters with some below detection limit values (less than or equal to 70 percent), the representative value is the Kaplan Meier mean concentration. For parameters with greater than 70 percent below detection limit values, the representative concentration is the median concentration with the detection limit substituted for below detection limit results. The *Final Baseline Surface Water Quality Technical Report* (ERO Resources Corp. 2011c) discusses the methods used in determining representative concentrations in ambient surface waters along with details concerning data reduction methods and outlier identification. The same methods were applied in determining the representative groundwater concentrations. The data outliers removed along with a discussion of the data reduction methods are provided in Appendix K-11. The agencies reviewed and summarized available water quality data collected through 2012. Any data collected after 2012 has not been reviewed as part of this EIS evaluation.

Wastewater Quality

Consistent with the recommendations of the Global Acid Rock Drainage guide (International Network for Acid Prevention 2010) for mine planning, feasibility and design stage projects, potential water quality impacts were predicted for material types based on geological descriptions and mineral deposit models. Changes in the chemistry of water interacting with rock exposed in underground mine workings, backfilled waste rock, surface facilities constructed with waste rock, and tailings were evaluated using available metal mobility and kinetic analyses of rock from the Montanore, Rock Creek, and Troy deposits (see section 3.9.4, *Environmental Geochemistry*). Estimates of wastewater quality (Table 120) relied on monitored water quality from the Libby Adit, the waste rock stockpiled at the Libby Adit, and the Troy Mine underground workings, tailings impoundment, and decant pond (Appendix K). Because no organic nitrogen data were available for the mine and tailings water from the Troy mine, total nitrogen concentrations provided in Table 120 for mine and tailings water are only for the total of nitrate, nitrite and ammonia concentrations. A *Final Baseline Surface Water Quality Technical Report* (ERO Resources Corp. 2011c) provides the methods used in reducing the data, identifying outliers, and determining representative concentrations in wastewater. Representative wastewater concentrations were updated using available water quality data collected through 2012. A discussion of the geochemistry information used in developing wastewater quality is in section 3.13.3.3, *Geochemistry of Exposed Materials*. Section 3.13.4.5, *Uncertainties Associated with the Water Quality Assessment* discusses the uncertainties of the concentrations provided in Appendix K.

Three aspects of water management at Montanore in Alternatives 3 and 4 would likely result in lower concentrations of total dissolved solids, metals, and nutrients in tailings water quality than found at the Troy Mine. 1) Mine and adit water would not be used for ore processing, but would be treated year-round and discharged from the Water Treatment Plant. 2) Pumpback wells at the impoundment would pump groundwater mixed with tailings seepage back into the impoundment. The estimated seepage at full capacity is 25 gpm and the estimated pumping rate of all pumpback wells is 250 gpm. Groundwater at both impoundment sites would have lower concentrations of all parameters than tailings water. 3) MMC would divert water from Libby Creek during high flows for mill use. MMC estimates 125 million gallons of water would be needed during an average precipitation year. The makeup water would be stored in the impoundment, the Seepage Collection Pond, or the mine/yard pond at the Libby Plant Site. Libby Creek surface water would have lower concentrations of all parameters than tailings water.

Table 120. Estimated Adit, Mine, and Tailings Wastewaters and Water Treatment Plant Treated Water Quality for Alternatives 2, 3, and 4.

Parameter	Construc-tion Adit Water	Post-Construc-tion Adit Water	Mine Water Operations	Mine Water Post-Operations	Tailings Water	Water Treatment Plant Discharge
Total dissolved solids	122	114	121	108	266	110
Ammonia, as N	<0.65	<0.050	<1.6	<0.16	4.4	0.70
Nitrate, as N	<37	<0.12	**3.1**	**0.76**	**13**	0.60
Total Nitrogen	<38.1	<0.13	**<4.7**	**<0.92**	**17.4**	1.30
Total Phosphorus	<0.026	<0.0073	0.096	<0.10	0.086	0.01
Aluminum	<0.014	<0.011	0.075	**<0.050**	<0.13	0.090
Antimony	<0.00069	<0.00032	<0.0088	<0.0094	0.023	0.0010
Arsenic	<0.0057	<0.0011	<0.018	<0.0031	<0.0017	0.00010
Barium	0.014	0.012	0.068	**0.043**	<0.11	0.20
Beryllium	<0.00080	<0.00080	**<0.0010**	**<0.0010**	<0.0010	0.00020
Cadmium	<0.000080	<0.000080	0.0015	**0.00040**	0.00097	0.000010
Chromium	<0.00047	<0.00054	<0.0010	**<0.0010**	<0.0010	0.0060
Copper	<0.0012	<0.0010	0.042	0.065	0.026	0.0035
Iron	<0.017	<0.017	<0.15	<0.020	0.050	0.13
Lead	<0.00010	<0.00017	0.0080	**0.0060**	<0.0044	0.00035
Manganese	<0.0050	<0.0050	0.21	0.067	0.51	0.070
Mercury	<0.000022	<0.000017	<0.0000050	**0.00059**	<0.0000050	0.000010
Nickel	<0.00075	<0.00055	<0.010	**<0.010**	<0.010	0.0030
Selenium	<0.0010	<0.0010	0.0020	**<0.0010**	<0.0013	0.0015
Silver	<0.00020	<0.00025	**0.075**	**0.0040**	**0.0017**	0.00040
Zinc	<0.010	<0.012	<0.012	<0.013	<0.010	0.030

All concentrations are in mg/L. All metal concentrations are dissolved metals unless otherwise noted.
Bolded nitrate concentrations indicate analyses were for nitrate plus nitrite.
Bolded total nitrogen concentrations do not include organic nitrogen because organic nitrogen data were not collected at the Troy mine for mine and tailings water.
Bolded metal concentrations are total results due to either lack of dissolved data or dissolved data that were below the laboratory detection limit with the detection limit being greater than the lowest water quality standard.
Concentrations presented with a < symbol had at least one sample with a reported concentration less than the detection limit used in calculating representative values; detection limit used in calculating representative value when reported concentration was below the detection limit.
Source: Appendices G and K.

Underground workings would expose zones of ore and waste rock to groundwater, with relatively low reactive surface area. Most sulfide and metal-bearing minerals are encapsulated within silica in the Revett Formation and water quality impacts would likely be minimal. Waste rock backfilled into underground workings would be variably reactive; the extent of sulfide oxidation and metal release would depend on the surface area of the backfill, as well as the relative conditions of saturation and oxygen availability. For this assessment, water interacting with ore and waste rock exposed in underground workings was estimated using the water chemistry measured in the Troy Mine adit, where comparable zones of in-place ore and waste, and backfill deposits, are exposed to groundwater. Underground workings in ore would be minimal during the Evaluation Phase. Any ore that was stockpiled early in mine life would be stockpiled in the tailings impoundment, placed on a liner at the waste rock stockpile area in the tailings impoundment, or stored at the stockpile area. Any seepage water from the ore would be collected and re-used in the mine or treated. Unsaturated conditions expected to exist underground during the Construction and Operations Phases are represented with operational monitoring data from the Troy Mine (Table 120; Appendix K-8). The conditions expected at closure are represented with water quality data collected at the Troy Mine during a period of interim closure between 1993 and 2004 when dewatering occurred during most of the period and the majority of the underground workings remained unsaturated. The results of laboratory kinetic tests generally agree with the monitoring data, although some differences in metal concentrations (relative magnitude, dissolved vs. total, etc.) were observed that would be addressed during Evaluation Phase testing. Future geochemical analyses of metal release potential for waste rock (see Appendix C) would be used, together with monitoring of underground water quality during operations, to address uncertainty about the contribution from backfilled waste rock and refine long-term predictions of water quality for underground workings.

Waste rock would be used for tailings dam construction in all mine alternatives and for plant site construction in Alternative 2. Any rock with a potential for acid generation or trace metal release would be placed as backfill. As kinetic and metal mobility test data are limited for waste rock weathering in the surface environment, the best available data are from the water sump for Prichard and Burke waste rock deposited on a liner at the Libby Adit Site. Data from water in the sump at the Libby Adit waste rock stockpile (Appendix K-10) were used to represent changes in water quality related to waste rock to be used at the impoundment site.

The tailings would have a low residual sulfide content after ore removal, and low potential for acid generation under either saturated (during operations) or unsaturated conditions (post-closure), but due to its relatively high surface area would release trace quantities of metals into solution. This conclusion is consistent with monitoring data from the Troy tailings impoundment, as well as kinetic and metal mobility tests of Montanore tailings conducted before 1992, and with the results of the tailings analysis from Rock Creek. Due to the scale effects of surface area and water flux on metal concentrations predicted for the tailings impoundment, the best available data for the assessment are the field-scale water quality monitoring results from the Troy impoundment (Appendix K-9). The specific identity and concentrations of metals would be re-evaluated when a bulk composite sample of ore could be collected during the Evaluation Phase and tested metallurgically to produce tailings for further testing (see Appendix C). This would allow consideration of any changes in water quality that could result from dewatering at post-closure.

Nitrate concentrations are less affected by the primary mineralogy of the rock than by the blasting practices used in mining. Increased nitrate concentrations are expected in water intercepted near blasted zones. Nitrate and ammonia concentrations of the wastewater from the mine and adits are not known. Data from the Libby Adit during the construction by NMC and from the nearby Troy Mine show a wide range of nitrate and ammonia concentrations. For water pumped from adits during construction, the nitrate concentration range is 0.0096 to 687 mg/L, with a representative concentration of <37 mg/L, and the ammonia concentration range is 0.010 to 21.9 mg/L, with a representative concentration of <0.65 mg/L (Appendix K-5). Additional data on nitrate and ammonia concentrations would be collected during the Evaluation Phase. The agencies used the Libby Adit water quality data collected by NMC after adit construction ceased and nitrate and ammonia concentrations were not affected by blasting to develop an estimate of nitrate and ammonia concentrations in wastewater from post-construction adits. From the post-construction adits, the representative nitrate concentration is estimated to be <0.12 mg/L and the average ammonia concentration is <0.050 mg/L in wastewater (Appendix K-6).

Stream Temperature

Stream temperature is an important criterion for aquatic life and Montana has surface water aquatic life standards for temperature that restrict temperature changes. For bull trout, water temperatures ranging from 36° to 59°F are needed, with adequate thermal refugia available for temperatures at the upper end of this range. Constant temperatures greater than 60°F have been shown to be intolerable for bull trout (Maret *et al*. 2005). Direct solar radiation is the primary contributor to daily fluctuations in stream temperature, but stream temperature is influenced by many factors: air temperature, topography, weather, shade, streambed substrate (bedrock versus gravel or sandy bottoms), stream morphology, the amount of subsurface streamflow, and groundwater inflows (USDA Pacific Northwest Research Station 2005). The project may affect stream temperatures by vegetation clearing, discharge of treated water from the Water Treatment Plant, decreased streamflow due to direct diversions, and changes in groundwater discharge to area streams. Due to the numerous factors affecting stream temperatures and the constantly changing stream temperature regime that occurs, it is difficult to predict how the project may alter stream temperature, or to what extent stream temperatures may be changed.

The temperature of the discharge of mine and adit water is expected to be between 56° and 65°F based on measured temperatures of the Water Treatment Plant influent (MMC 2008, 2009b, 2010, 2011b, 2012g, 2013). The temperature of the tailings water discharge during the Closure and Post-Closure Phases is expected to be close to ambient temperature at the time of discharge from the Water Treatment Plant, except during the winter months, when it may be warmer. Discharges during operations would be a mixture of mine and adit water, and water stored in the tailings impoundment. Water discharged from the Water Treatment Plant, if discharged to the percolation pond next to Libby Creek, would cool as it flowed from the percolation pond via the subsurface to the creek. Discharges to either the percolation pond or directly to Libby Creek would cool further when mixed with receiving creek water.

In Alternative 2, discharges would be to groundwater at the LAD Areas and to either groundwater or surface water from the Water Treatment Plant at the Libby Adit Site. In Alternatives 3 and 4, discharges would be to either groundwater or surface water from the Water Treatment Plant at the Libby Adit Site. Temperature was not included in the mass balance calculations because the temperature of the discharge water and the receiving water would vary during the year. For all Water Treatment Plant discharges, the DEQ during the MPDES permitting would determine effluent limits for each necessary parameter at each outfall that were protective of aquatic life. Temperatures downstream of the Water Treatment Plant outfalls would be monitored during water resources and aquatic biology monitoring.

Vegetation clearing would occur at stream crossings of new or widened roads and the transmission line. The removal of all riparian vegetation for road construction and reconstruction and riparian vegetation taller than 10 feet for the transmission line along streams would increase direct solar radiation to streams. The transmission line alternatives would cross between four and five perennial streams and numerous smaller streams (Table 77). Vegetation clearing would be up to 150 feet wide in Alternative B and up to 200 feet wide in the other alternatives. Clearing may increase stream temperature at and for a short distance below the stream crossings, but it is difficult to predict the magnitude of the effect due to other factors affecting stream temperature and the constantly changing stream temperature regime.

The pumpback wells and any other diversions (such as make-up wells) would reduce streamflow. For example, at PM-1200 in Poorman Creek, the estimated $7Q_{10}$ flow is predicted to be reduced by up to 12 percent. It is possible that this might increase the stream temperature during low flows, but forest shading and flow in the gravel streambed substrate, as well as groundwater supply to the stream, may prevent or minimize such a temperature change.

The reduction in bedrock groundwater inflows to analysis area streams due to mine inflows may increase stream temperatures where bedrock groundwater is the major component of baseflow. Bedrock groundwater flow to streams is fracture controlled and does not occur uniformly along any stream reach. It is difficult to predict how, when and where reduced bedrock inflows may affect stream temperatures, or if such changes would be measureable.

Given all of the factors that affect stream temperature, as well as the constantly changing stream temperature regime, it may not be possible to separate any effect of the mine alternatives on stream temperature from other effects. The proposed water resources and aquatic biology monitoring for Alternative 3 is presented in Appendix C. Stream temperature is not discussed further.

Erosion and Sedimentation

The agencies analyzed the potential effects of facility construction and diversions on erosion and sedimentation both qualitatively and quantitatively. The effects of facility construction were qualitatively analyzed. In all mine alternatives, the proposed Rock Lake Ventilation Adit would be on a steep, rocky slope about 800 feet east of and 600 feet higher than Rock Lake. Because the total disturbance area for this adit would be small (about 1 acre), any effects would be minor and are not discussed further.

All mine and transmission line alternatives would require the construction of new roads, and the use of closed roads. Road construction and reconstruction is often considered the largest source of sediment in mining and timber harvest areas due to the removal of vegetation and construction of cut and fill slopes that expose large areas subject to erosion (Belt *et al.* 1992). To mitigate for project access effects on grizzly bears, some roads that are currently open would be closed, most before the Evaluation Phase and all before the Construction Phase. Other roads would be closed at the end of operations.

The agencies used Forest Service interfaces for the Water Erosion Prediction Project Computer Model (FS WEPP) (USDA Forest Service 1999a) to quantitatively evaluate erosion and sediment delivery from forest roads that would be used for each mine alternative and each transmission line alternative, and for roads that would be closed for grizzly bear mitigation. It was assumed that roads would be graveled and use would be high. Short new access roads would be constructed for the transmission line alternatives. To complete the FS WEPP analysis (KNF 2013), the agencies assumed that the access roads would be located within 100 feet of surface water, would be surfaced with native material, would be 30 feet wide and would have a 2 percent gradient. Most roads used in the transmission line analysis would be greater than 100 feet from surface water. Based on prior road decommissioning activities on the Libby Ranger District, closed roads are expected to deliver sediment for up to 2 years after treatment. Revegetation and stabilization is complete by the end of the second year after the work was completed. The KNF used a 30-year analysis period to assess effects (KNF 2013). The accuracy of the predicted values from the model is, at best, within ±50 percent. Actual sediment delivery rates to streams would be highly variable due to large variations in local topography, climate, soil properties, and vegetation properties; predicted rates are only an estimate of a highly variable process (USDA Forest Service 1999a). Data were collected in the summer of 2010 for use in the WEPP model to generate results at a drainage-area level.

The FS WEPP:Road Batch is designed to predict sediment delivery from roads to streams without BMPs or mitigations such as surface drainage, ditch relief, or paving. BMPs would be used during road construction and closure activities to reduce the amount of sediment reaching streams. BMPs would be the most effective way to minimize sediment delivery from affected forest roads and are estimated to be between 88 and 99 percent effective (KNF 2002b, DNRC 2010). The agencies used the lower end of BMP effectiveness (88 percent) in the WEPP analysis (KNF 2013).

3.13.3 Affected Environment

3.13.3.1 Surface Water

3.13.3.1.1 Streams

The representative quality of the mine area streams is summarized in Appendix K-1. The surface waters in the analysis area are a calcium-bicarbonate water. Total suspended solids, total dissolved solids, turbidity, major ions, and nutrient concentrations are all low, frequently at or below analytical detection limits. Metal concentrations are generally low with a high percentage of below detection limit values (exceptions include aluminum and barium). Analysis area streams are poorly buffered due to low alkalinities. Consequently, surface waters tend to be slightly acidic, with most pH values slightly below 7. The acidity has two likely natural sources: organic acids originating from surrounding coniferous forests and dissolved carbon dioxide in surface water and groundwater draining into the area streams. Median water hardness in area streams are typically less than 35 mg/L, with upper stream reaches having median hardness values typically less than 10 mg/L. Surface water in the Poorman Impoundment Site, some of which originates from bedrock springs, had pH values ranging from 7.2 to 8.2 and higher ion concentrations than other surface water in the project area (Kline Environmental Research 2012).

3.13.3.1.2 Springs

The representative quality of the mine area springs is summarized in Appendix K-2. Springs from all areas are mostly calcium bicarbonate water, but some are sodium bicarbonate water. Springs with higher total dissolved solids and metal concentrations (*e.g.*, SP-14 and SP-30 shown on Figure 70) are a result of longer subsurface flow paths than other springs. For example, a spring located directly above Rock Lake (SP-1R) appears to receive mostly shallow groundwater, whereas a spring below Rock Lake (SP-3R) appears to receive a combination of shallow and deeper groundwater; both springs are shown on Figure 68.

3.13.3.1.3 Lakes

The representative quality of the mine area lakes is summarized in Appendix K-3. Lakes located in or near the CMW are quite dilute; the primary source of dissolved solids and nutrients is bedrock groundwater (Gurrieri and Furniss 2004). Groundwater entering the lakes can be the major source of nutrients for phytoplankton in the lakes. An investigation of Rock Lake completed in 1999 (Gurrieri and Furniss 2004) found that during the ice-free season, groundwater contributed 71 percent of the minerals to the lake, surface water contributed 25 percent, and rainfall contributed 4 percent. Seasonal variations in the water quality of Rock Lake indicate that the volume of inflow from various sources (snowmelt, rainfall, shallow and deep groundwater) varies proportionally during the year. Because the watershed above Rock Lake consists of highly resistant bedrock with little vegetation and soil cover, snowmelt and surface water entering the lake are very dilute (very low dissolved solids). Because the Libby Lakes are extremely dilute and very vulnerable to atmospheric acid deposition, and possible indicators of climate change, they were monitored beginning in 1991 (Grenon and Story 2009; McMurray 2013).

In July through September 2013, MMC measured specific conductance, pH, temperature, dissolved oxygen and turbidity in the outlets from Rock Creek and Wanless Lake, the latter a benchmark monitoring location outside of the range of influence of expected mine or adit inflows. The water quality results were similar. Specific conductance was slightly higher in water at the Wanless Lake outlet (ranging from 3 to 4.5 µS/cm higher in the Wanless Lake outlet). MMC also measured specific conductance, pH, temperature, and dissolved oxygen in Wanless Lake. All of the specific conductance measurements for Rock and Wanless lakes were less than 25 µS/cm, indicating quite dilute lakes.

3.13.3.2 Groundwater

Several monitoring wells installed adjacent to the Libby Adit Site, near the LAD Areas or at the proposed location of the Alternative 2 and 4 tailings impoundment are screened in the unconsolidated glacial or fluvial sands and gravels (Figure 68 and Figure 70). Water samples from the Libby Adit represent the quality of water in fractured deep bedrock. The sources of the adit water were generally more than 1,000 feet below the ground surface and seasonal trends in water quality were not observed in the data, as might be expected in shallow groundwater influenced by surface water infiltration. Appendix K-4 summarizes the quality of shallow groundwater at the Libby Adit Site, LAD Areas, Little Cherry Creek Impoundment Site, and deep bedrock groundwater from the Libby Adit Site. For purposes of analysis, it is assumed that the groundwater quality under the Poorman Tailings Impoundment Site is the same as under the Little Cherry Creek Tailings Impoundment Site because the two locations are adjacent to each other and are geologically similar.

Groundwater samples from monitoring wells in the Libby Adit, Little Cherry Creek tailings impoundment, and LAD Area sites show that existing groundwater in the unconsolidated sediments is a calcium-bicarbonate or calcium-magnesium bicarbonate type with low total dissolved solids concentrations, low nutrient concentrations, and dissolved metal concentrations that are typically below detection limits. Barium and manganese were the only metals consistently detected in groundwater samples. The Libby Adit wells appear to be influenced by seasonal infiltration of surface water because they have seasonal fluctuations in ion concentrations (generally low in May through July, and higher in the fall through winter months). The Little Cherry Creek tailings impoundment and LAD Area wells have consistently low ion concentrations that do not appear to fluctuate seasonally. The pH of groundwater is slightly acidic in the various facility areas (Appendix K-4). Bedrock groundwater has higher ion concentrations, especially sodium and bicarbonate. The pH is somewhat alkaline, and the water is harder.

3.13.3.3 Geochemistry of Exposed Materials

3.13.3.3.1 Ore

Because there has been no historical development of ore within the Montanore deposit, the proposed action would modify the existing underground environment. Low concentrations of dissolved copper, manganese, and zinc are predicted for release when ore and waste rock in the adit walls are exposed to air and water. The sulfides contained in the ore are predominantly non-acid generating, although some potentially reactive sulfides may be present in altered waste zones (Enviromin 2013b). The massive nature of the quartzite that hosts Revett-style ore would limit the surface area exposure of potentially reactive sulfides and substantially reduce the potential for acid generation by exposed ore. The small percentage of sulfides that would be exposed is expected to oxidize to form secondary copper oxide and sulfate minerals with variable solubilities. These secondary minerals would have potential to release metals into groundwater at a near-neutral pH. Results reported for dissolved metal concentrations in Troy Adit mine water, which are believed to result from this process, are consistent with the metal release concentrations reported in metal mobility and kinetic tests of rock from Montanore. Higher total recoverable metal concentrations are expected in groundwater samples that contain sediment, which reflects the importance of metal transport by sediment. For these reasons, any water from underground workings would be treated before discharge in Alternatives 3 and 4 to meet MPDES-permitted effluent limits.

3.13.3.3.2 Tailings

During operations, ore would be shipped to the mill for processing, where 90 percent of the sulfides would be removed. Following grinding, pH adjustment, and removal of sulfide during processing, the homogenous tailings would have an elevated pH of 9 or greater, with a low sulfide content of less than 0.1 percent. Due to the elevated pH and low sulfide content, acid generation from tailings would be unlikely. Tests of metal mobility in tailings, and operational monitoring at the analogous Troy Mine, suggest that some metals would be mobile in tailings effluent at a near-neutral pH, particularly during operations when suspended sediments may transport adsorbed metals. These metals include aluminum, cadmium, copper, iron, lead, manganese, and silver. Nitrate and ammonia concentrations also would be elevated. Only dissolved constituents would have the potential to move beyond the impoundment and potentially affect groundwater and surface water quality, and it is likely that mobile concentrations would decrease when suspended solids were diminished at closure. Tailings would be placed in the impoundment during operations, under saturated conditions, and remain exposed to weathering processes in the tailings impoundment under unsaturated conditions at closure. The specific concentrations of metals would be re-evaluated in tests conducted during the Evaluation Phase (see Appendix C) when a bulk composite sample of ore would be collected from the evaluation adit and metallurgically processed to produce tailings for further kinetic leach testing (see Appendix C). This testing would allow consideration of any changes in water quality that could result from dewatering of tailings post-closure.

3.13.3.3.3 Waste Rock

Waste rock to be mined at Montanore has a low risk of acid generation, but may release low concentrations of metals. A relatively low tonnage of reactive waste rock would be produced, which would be placed as backfill in underground workings and stored under saturated, anaerobic conditions. The same volume of each lithology would be produced under each alternative, and waste rock would be used for tailings dam construction in all mine alternatives and for Plant Site construction in Alternative 2.

The environmental geochemistry data indicate that a portion of the lower Revett Formation has the potential to generate acid, while other portions of the formation do not. Kinetic data support the potential for weak acid generation from the lower Revett altered waste zones, particularly the barren lead zone that separates the two ore zones (Zones 1 and 2) (Figure 11 in Chapter 2). This zone has the potential to reduce the pH in water to 6 and release low concentrations of barium, copper, lead, manganese, and zinc. The risk to water quality would be mitigated by limiting the mining of rock within the barren lead zone. Additional characterization as development advanced through the lower Revett altered waste zones would be important for selection of waste rock for use in tailings dam construction, and would also be of value in understanding potential changes in mine water chemistry resulting from backfilling of reactive waste rock. Rock in the lower Revett would be exposed in workings during the Evaluation, Construction, and Operations Phases of the project.

Comparison of the static results with kinetic test data indicates that static test data overestimate the potential for acid formation from the Prichard Formation waste rock, a conclusion that is supported by the neutral mine drainage observed in the exposed section of Prichard Formation in the Libby Adit and from the rock stockpiled at the Libby Adit Site. In spite of a neutral pH, Prichard Formation rock has the potential to release low quantities of arsenic, iron, manganese, and zinc. Metal release information would also be important for final Water Treatment Plant design. The majority of the exposure of rock from the Prichard and Burke formations would occur during adit construction, through operations, and into closure. Waste mined from the Burke Formation appears unlikely to generate acid, although additional data would be collected to confirm this.

3.13.3.4 Climate Change

Section 3.10.3.4, *Climate Change* in the *Groundwater Hydrology* section discusses projected climate trends for the Columbia River Basin in general. Several variables potentially affected by climate change, such as water temperature, flow, runoff rate and timing, and the physical characteristics of the watershed, affect water quality (Lettenmaier *et al*. 2008). While it is likely that climate change will affect the capacity of surface water ecosystems to remove pollutants and improve water quality, the timing, magnitude, and consequences of these impacts are not well understood (Lettenmaier *et al*. 2008).

3.13.4 Environmental Consequences

This section describes the anticipated changes in surface water and groundwater quality for each alternative. This includes analysis area streams, lakes, springs, and aquifers underlying the mine facilities. Potential direct and indirect effects of the project are described, as are potential cumulative effects that may occur as a result of the mine and transmission line alternatives and identified reasonably foreseeable actions.

3.13.4.1 Alternative 1 – No Mine

In this alternative, MMC would not develop the Montanore Project. Any existing exploration-related or baseline data collection disturbances by MMC would be reclaimed in accordance with existing laws and permits. The DEQ’s approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit Evaluation program that did not affect National Forest System lands. Discharges from the Water Treatment Plant would continue until the adit was plugged.

3.13.4.2 Alternative 2 – MMC Proposed Mine

Development of the Montanore Project would require construction of project facilities, such as a mill, tailings impoundment, adits, and access roads. In MMC’s proposal, the mill and mine production adits would be located in the upper Ramsey Creek drainage, about 0.5 miles from the CMW boundary. An additional adit on MMC’s private land in the Libby Creek drainage and a ventilation adit on MMC’s private land east of Rock Lake would be used for exploration and ventilation. A tailings impoundment proposed in the Little Cherry Creek drainage would require the diversion of Little Cherry Creek. MMC anticipates and the agencies concur that proper management of explosives and use of emulsions would reduce nitrate concentrations from those detected during the initial Libby Adit construction. Adit and mine water would be treated, if needed, before discharging to LAD Areas for secondary treatment. Two LAD Areas between Poorman Creek and Ramsey Creek are proposed to allow for discharge of excess mine water using sprinkler irrigation of water on the land surface. A portion of the waste rock resulting from adit development may be stored temporarily on an unlined surface at LAD Area 1, and at the Libby Adit Site. The total area of disturbance for Alternative 2 would be 2,582 acres.

Sanitary waste would be collected and shipped off-site for treatment and disposal. Handling sanitary waste in this manner would not be feasible because the City of Libby would not accept sanitary waste produced at the operation and no other feasible off-site option was available.

3.13.4.2.1 Evaluation and Construction Phases (Years 1-5)

Groundwater

Mine Area

During the Evaluation and Construction Phases, groundwater would flow toward the adit and mine openings, and the quality of groundwater surrounding the adits and mine would not be adversely affected by the mine. In the streams whose baseflow would be reduced as a result of mining, water quality changes may occur. Deeper bedrock groundwater is likely to have higher total dissolved solids concentrations than shallow groundwater or direct runoff to streams, so a decrease in the deeper bedrock groundwater contribution to streamflow may result in lower total dissolved solids concentrations in streams.

The Libby Lakes are located at an elevation of about 7,000 feet, and are perched above the potentiometric surface. The lakes lie on a series of faults and vertically oriented bedding planes, but there are no observations, data, or numerical model results to indicate that the lakes are hydraulically connected to the deep bedrock potentiometric surface. It is unlikely that the Libby Lakes would be affected by mining activities during these phases. Because deep bedrock groundwater is a contributor to Rock Lake throughout the year (Gurrieri 2001), mining may affect the water quality of Rock Lake. There are subtle differences in the quality of shallow and deeper groundwater, both of which are source waters for Rock Lake, as is surface water runoff (Gurrieri 2001). Baseline water quality data for Rock Lake are provided in Appendix K-3. It may be difficult to differentiate changes in water quality from pre-mining water quality variability. If less groundwater were contributed to Rock Lake, total dissolved solids, silica (needed by diatoms), and nutrient concentrations may decrease in the lake.

Depending on the ratio between shallow and deep groundwater contribution to area springs, water quality changes may be slight and not detectable. In the case of springs that receive a large portion of their flow from deep groundwater, total dissolved solids concentrations may decrease as the shallow groundwater accounts for a larger proportion of the total flow. The only springs whose water quality may be adversely affected by the mine would be those in the analysis area located below an elevation of about 5,000 to 5,600 feet (see section 3.10.4.3.1, *Seeps and Springs* of the *Groundwater Hydrology* section).

Libby Adit Area

Mine and adit water treated at the Water Treatment Plant at the Libby Adit Site (up to 500 gpm in Alternative 2) may be discharged to groundwater via a percolation pond located in the alluvium adjacent to Libby Creek or, when the percolation pond reached capacity, to Libby Creek. The pH of the discharge of mine and adit water is expected to be about 8, slightly greater than instream pH values of between 6.5 and 7.5 in Libby Creek. Water discharged from the Water Treatment Plant, if discharged to the percolation pond next to Libby Creek, would mix with groundwater with a pH of about 6.5. Mixing would also occur within an authorized mixing zone in Libby Creek. After mixing, the expected quality of the treated water would be below BHES Order limits and applicable nondegradation criteria in surface water and groundwater. During the MPDES permitting process, the DEQ would determine if the groundwater mixing zone in the current permit would be renewed.

Tailings Impoundment Area

No water would be stored at the tailings impoundment site during the Evaluation Phase. Groundwater quality in the area would not be affected. The Starter Dam would be constructed partially with waste rock. Limited testing of waste rock excavated from the Libby Adit indicated waste rock leachate contained elevated nutrient concentrations (Table 94). Nitrate concentrations may increase beneath the Starter Dam. MMC committed to implementing seepage control measures, such as pumpback recovery wells, if required to comply with applicable standards. Seepage pumpback wells could be installed along the downstream toe of the tailings dam. Given the heterogeneity of the foundation soils, additional wells could be required to ensure that all flow paths were intercepted. The wells may require active pumping, depending on the artesian pressures within the wells (Klohn Crippen 2005).

After the Starter and Seepage Collection Pond dams were constructed, precipitation and runoff would be captured behind the dams. Some of the area behind the Starter Dam would be lined. Some seepage not collected by the Seepage Collection System would reach groundwater. Water stored behind the Starter Dam would be of generally good quality because it would be mostly precipitation and surface water runoff. Water stored in the impoundment would not affected groundwater quality.

LAD Areas

When mine and adit water was discharged to the LAD Areas, it would mix with precipitation, and much of it would evapotranspire. The quality of the water before chemical and biological treatment within the plant root/soil matrix would change as a result of dilution by rain water, then concentration of about 90 percent (on average, depending on the season of discharge, weather conditions, soil moisture levels, etc.) of this water could be lost to the atmosphere via evapotranspiration. Resultant nutrient and metal concentrations were calculated and used for the mass balance analysis (Appendix G). The water would then be treated within the plant root/soil matrix.

Land application can substantially reduce suspended sediment, nitrogen, phosphorus and metal concentrations in the applied water. Nitrogen removal occurs through vegetation uptake, biological reduction through nitrification/denitrification in the soil, and ammonia volatilization. The main concern associated with land application is the potential for nitrate to be transported to groundwater (Environmental Protection Agency 2006b). Nitrate removal is site- and effluent-specific; removal depends on application rate, soil physiochemical properties, soil hydraulics, soil moisture, soil organic content vegetation types, slope, and temperature. Ammonia removal is by volatilization, uptake by vegetation, and adsorption by clay minerals in the soil; its removal depends on temperature, pH, soil characteristics and soil water content. Phosphorus removal is accomplished through plant uptake and by fixation in the soil matrix. Metals are removed by adsorption, precipitation, ion exchange, biogeochemical reactions, uptake by plants and microorganisms, and complexation (Environmental Protection Agency 2006b). Metal removal is site- and effluent-specific and depends on vegetation type, soil characteristics, pH, and temperature.

Due to the many variables that have not been specifically defined for the LAD Areas, the agencies could not determine specific treatment rates for nitrate, nitrite, ammonia, total nitrogen, total phosphorus and metals. The BHES Order requires the DEQ to review design criteria and final engineering plans to determine that at least 80 percent removal of nitrogen would be achieved by LAD treatment. Removal rates for ammonia, nitrate, and nitrite cannot be determined until LAD Area final engineering plans, design criteria, and soil studies were submitted and monitoring commenced. Treatment rates for nitrogen compounds appear to vary widely, ranging from 50 to 90 percent for total nitrogen (Environmental Protection Agency 2002). Maximum nitrogen removal occurs when nitrogen is applied in the ammonia or organic form rather than the nitrate form (Georgia Department of Natural Resources 2006; Environmental Protection Agency 2006b). Ammonia represents the reduced (less oxidized) form of nitrogen, while nitrate represents the oxidized form. Ammonia is expected to be present in wastewater used on the LAD Areas. Nitrates are more readily taken up by plants, while ammonia is more readily adsorbed by soils. Phosphorus removal by land application has shown a wide range of removal rates ranging from 20 to 100 percent (EPA 1974), and is a function of residence time and travel distance involving complex physical, biochemical, and chemical interactions, soil type and vegetation type.

In the agencies' analysis, land application treatment rates were assumed to be 50 percent for nitrate, ammonia, total nitrogen, total phosphorus, and some metals. If needed, primary treatment of nitrate would occur before land application disposal. For zinc, aluminum, barium and manganese, a 10 percent removal was assumed, and for copper and nickel a 90 percent removal was assumed. A report prepared for NMC (Camp Dresser and McKee, Inc. 1991) on soil attenuation in the analysis area showed high copper attenuation in the analysis area soils. Zinc may be taken up by vegetation, but does not, in general, sorb readily on soils. Manganese also does not sorb readily on all soil types. In the agencies' analysis, it was assumed that 90 percent of the zinc and manganese percolated to groundwater.

The predicted concentrations in groundwater after mixing beneath the LAD Areas for each mine phase, when an estimated rate of 130 gpm of water was sent to the LAD Areas for treatment (see section 3.10.4.2.1, *LAD Areas* of the *Groundwater Hydrology* section), are provided in Table 121. Predicted concentrations in groundwater would be slightly better during the Post-Closure Phase than those shown for the Closure Phase. If land application of excess water resulted in BHES Order limit or nondegradation criteria exceedances, MMC would treat the additional water at the Water Treatment Plant instead of discharging it to the LAD Areas. No natural attenuation or removal mechanisms for total dissolved solids in groundwater is expected; dissolved solids concentrations in groundwater may increase based on residence time. No natural attenuation or removal is expected for nitrate in groundwater. Analyses of the Troy Mine decant pond disposal system by Hydrometrics (2010), Land and Water Consulting (2004), and Camp, Dresser and McKee (2010), indicated natural attenuation or removal of metals from tailings impoundment seepage would occur, including antimony, arsenic, copper, and mercury. These investigations are described under the Operations Phase. Based on these findings, the predicted antimony, arsenic, copper, and mercury concentrations in groundwater (Table 121) may be higher than would actually occur during the Evaluation, Construction, Closure and Post-Closure Phases. Oxygen-ation of the mine and adit water from the use of sprinklers at the LAD Areas may result in the precipitation of iron oxide and manganese oxide on the land surface. As a result, the predicted iron and manganese groundwater concentrations shown in Table 121 may be higher than would actually occur. The ambient manganese concentration in groundwater at the LAD Areas exceeds the BHES Order limit. Iron and manganese oxides are relatively insoluble, and if precipitated on the ground surface at the LAD Areas, would not dissolve. Although large runoff events may loosen the material and erode it downhill, the material would not reach surface water as most runoff would be captured by sediment ponds designed for a 10-year/24-hour storm. A larger storm event may result in iron and manganese precipitates eroding downhill to surface water.

Table 121. Predicted Concentrations in Groundwater after Mixing beneath the LAD Areas, Alternative 2.

Parameter	Ambient Concentration	Construction Phase	Closure Phase	BHES Order Limit[1]	Applicable Nondegradation Criteria Outside of a Mixing Zone		
					Ambient Concentration[2]	Trigger Value[3]	15% of Lowest Standard[4]
Total dissolved solids	63	**283**	**580**	200			
Nitrate	0.060	**<38**	**13**	10			
Antimony-T	<0.0030	<0.0022	**<0.025**			0.0004	0.0009
Arsenic-C	<0.0030	**<0.0076**	**<0.0033**		<0.0030		
Barium-T	<0.0067	<0.029	**<0.21**			0.002	0.15
Beryllium-C	<0.0010	<0.0007	<0.0007		<0.0010		
Cadmium-T	<0.00010	<0.00013	**<0.0011**			0.0001	0.000075
Chromium-T	<0.0010	<0.0010	<0.0015	0.02			
Copper-T	<0.0010	<0.00074	<0.0061	0.1			
Iron-H	<0.052	<0.043	<0.076	0.2			
Lead-T	<0.00034	<0.00019	<0.0011			0.0001	0.0023
Manganese	<0.081	<0.049	**<1.0**	0.05			
Mercury-T	<0.000020	**<0.000033**	<0.000015		<0.000020		
Nickel-T	<0.010	<0.0051	<0.0070			0.0005	0.015
Selenium-T	<0.0010	<0.00151	<0.0018			0.0006	0.0075
Silver-T	<0.00050	<0.00045	<0.0020			0.0002	0.015
Zinc-T	<0.010	<0.024	<0.024	0.1			

All concentrations are mg/L. All metal concentrations are for dissolved metals.
Method used to derive representative ambient water quality concentrations described in ERO 2011c. Concentrations presented with a < symbol had at least one sample with a reported concentration less than the detection limit used in calculating representative values; detection limit used in calculating representative value when reported concentration was below the detection limit.
No discharges to LAD Areas are projected to occur during the Operations Phase.
Predicted concentrations greater than BHES Order limits or applicable nondegradation criteria without additional primary treatment before land application are shown in **bold**.
[1] BHES Order limits apply to only to those parameters for which limits were set in 1992: total dissolved solids, nitrate, chromium, copper, iron, manganese, and zinc.
[2] No increase in ambient concentrations outside of a mixing zone designated by the DEQ applies to degradation determination in nondegradation review for arsenic, beryllium, and mercury.
[3] Trigger values apply to degradation determination in nondegradation review for antimony, barium, cadmium, lead, nickel, selenium, and silver.
[4] 15% of lowest standard only applies to degradation determination for concentrations of toxins (antimony, barium, cadmium, lead, nickel, selenium, and silver) outside of a mixing zone designated by the DEQ if the change in water quality exceeds the trigger value. The DEQ typically does not grant mixing zones for LAD Areas.
Source: Appendix G.

MMC requested a source-specific groundwater mixing zone for the LAD Areas in Alternative 2 (Geomatrix 2007b). A mixing zone is a limited area of a surface water body or a portion of an aquifer, where initial dilution of a discharge takes place and water quality changes may occur, and where certain water quality standards may be exceeded (ARM 17.30.502(6)). During the MPDES permitting process, the DEQ would determine if a mixing zone beneath and downgradient of the LAD Areas would be granted in accordance with ARM 17.30.518 and, if so, would determine its size, configuration, and location. If DEQ granted a mixing zone, water quality changes might occur, but BHES Order limits could not be exceeded outside the mixing zone, and for other water quality parameters, nondegradation criteria could not occur outside the mixing zone unless authorized by DEQ. The DEQ typically does not grant mixing zones for LAD Areas. The DEQ also would determine where compliance with applicable standards would be measured.

Surface Water

West Side Streams, Lakes, and Springs

During the Evaluation and Construction Phases, water quality in streams, lakes, and springs on the west side of the divide may be affected by reductions due to mine inflows in groundwater discharge to streams and Rock Lake. Because bedrock groundwater has higher dissolved solids concentrations, a reduction in groundwater discharge may result in surface water having lower dissolved solids concentrations. The change in groundwater discharge would be very small during these phases and it is unlikely that changes in water quality would be detectable.

East Side Streams, Lakes, and Springs

Effects of Mine Inflows and Discharges. Reductions in groundwater discharge to springs and streams east of the divide due to mine inflows would be small during the Evaluation and Construction Phases; changes in water quality would not likely be detectable. No lakes in the Libby Creek watershed would be affected by mine dewatering. Effects on the spring located close to the LAD Areas (such as SP-21 shown on Figure 70), assuming that shallow groundwater was a source of supply to such springs, would be similar to the effects on groundwater beneath the LAD Areas (Table 121).

Predicted concentrations after mixing at RA-600 (Ramsey Creek), PM-1200 (Poorman Creek), and LB-1000 (Libby Creek) following discharge at the Water Treatment Plant and the LAD Areas during Construction and Closure Phases are provided in Table 122, Table 123, and Table 124, respectively. The predicted concentrations for sites in Libby, Poorman, and Ramsey creeks were compared to the BHES Order limits, where applicable, or were evaluated based on the criteria for determining nonsignificant changes in water quality for parameters not listed in the BHES Order. Instream water quality concentrations during the Evaluation Phase would be similar to the Construction Phase. Predicted concentrations would be slightly better during the Post-Closure Phase than those shown in the tables for the Closure Phase. Predicted concentrations for all mine phases at numerous monitoring locations are presented in Appendix G.

Table 122. Predicted Concentrations with Land Application Treatment after Mixing at RA-600, Alternative 2.

Parameter	Ambient Concen-tration	Construction Phase	Closure Phase	BHES Order Limit[1]	Applicable Nondegradation Criteria Outside of a Mixing Zone

Source: Appendix G.

Nitrate and ammonia concentrations were added together to evaluate compliance with the BHES Order limit for total inorganic nitrogen (TIN). The BHES Order TIN limit (1 mg/L) during the Evaluation and Construction Phases at RA-400 and RA-600 are predicted to be exceeded without nitrogen pre-treatment. The TIN and total nitrogen limit during the Evaluation and Construction Phases at PM-1200 is predicted to be exceeded without nitrogen pre-treatment. The mass balance analysis also predicted exceedances of BHES Order limits or applicable nondegradation criteria for antimony, arsenic, and silver at RA-400. The mass balance analysis predicted exceedances of BHES Order limits or applicable nondegradation criteria for antimony, arsenic, and silver at RA-600, antimony, arsenic and silver at PM-1200, and arsenic at LB-1000. If land application of excess water resulted in BHES Order limit or nondegradation criteria exceedances, MMC would treat the additional water at the Water Treatment Plant instead of discharging it to the LAD Areas. Libby Creek is listed by DEQ as impaired for drinking water use due to exceedance of the human health standard for mercury; the predicted mercury concentration in receiving waters after mixing would be below the human health mercury standard for surface water (0.00005 mg/L). In 2014, the DEQ and the EPA issued TMDLs and a water quality improvement plan for the Kootenai River-Fisher River project area, which includes Libby Creek. The DEQ performed updated assessments on Libby Creek for metals impairment and did not identify metals impairment conditions in Libby Creek in the reassessment (DEQ and Environmental Protection Agency 2014). The impairment causes for this 1 mile section of Libby Creek (mercury) will be removed from the 2014 Water Quality Integrated Report.

During the MPDES permitting process, the DEQ would determine if a mixing zone in any stream receiving a discharge would be allowed and, if so, would determine its size, configuration, and location. MMC requested a source-specific mixing zone for lower Ramsey Creek, lower Poorman Creek, and Libby Creek (Geomatrix 2007b). The DEQ would make the same determinations regarding a mixing zone as it would for discharges at the LAD Areas.

Effects of Stormwater Runoff, Erosion, and Sedimentation. Until vegetation ground cover reached pre-disturbance levels, erosion rates would be higher than before disturbance and may increase stream sedimentation in and downstream of the analysis area. MMC would implement a SWPPP to minimize erosion and sedimentation from disturbed areas during construction and operations. The plan would address stormwater runoff from mine-related facilities for soil stockpiles, access/haul roads, adit pads not constructed of waste rock, and parking lots. The plan would describe the potential sources of stormwater pollution, pollution prevention practices, sediment and erosion control measures, runoff management, inspections, and reporting. BMPs would include ditches, sediment traps, and sediment retention ponds.

At the Ramsey Creek Plant Site, runoff from the top of the plant site pad area would be directed to a lined holding pond; runoff from the portal area and face of the plant site pad (including seepage) would be collected in ditches and directed to one or more sediment ponds. These ponds would be designed to contain runoff from a 10-year/24-hour storm of 2.4 inches. Runoff from storms greater than a 10-year/24-hour storm may overflow the sediment pond and enter Ramsey Creek. The effect on stream water quality may not be detectable during a storm event when the flow of Ramsey Creek would be high. Overflows could cause erosion and short-term increases in sediment in Ramsey and Libby creeks. The high streamflow present during such an event would likely distribute much of any released sediment well downstream to be deposited in floodplains, low gradient stream reaches, or transported to the Kootenai River. Once all plant site facilities were constructed, most of the surface area of the pad would be covered with impermeable materials, with any surface runoff directed to the lined holding pond.

The Ramsey Plant Site would be built within a Riparian Habitat Conservation Area (RHCA, discussed in the *Aquatic Life and Fisheries* section), as defined by the Inland Native Fish Strategy (INFS). A literature review associated with the development of the INFS (USDA Forest Service 1995) concluded that non-channelized sediment flow rarely travels more than 300 feet and 200- to 300-foot riparian buffers are generally effective at protecting streams from sediment from non-channelized overland flow (Belt *et al.* 1992). The Ramsey Plant Site would increase the potential for non-channelized sediment flow to reach Ramsey Creek.

Stormwater flow would be managed at the LAD Areas and the Little Cherry Creek Impoundment Site in the same manner as the Ramsey Plant Site. Stormwater runoff would be collected in ditches and directed to one or more sediment ponds. The ponds would be designed to contain runoff from a 10-year/24-hour storm. In the case of storms larger than a 10-year/24-hour storm, effects on nearby streams may be the same as discussed for the sediment ponds for the Ramsey Plant Site.

All clearing before construction at the LAD Areas would be located 300 feet or more from Libby, Poorman and Ramsey creeks. MMC would shut off sprinklers during periods of stormwater runoff, snowmelt, or saturated ground conditions, and MMC would not operate the LAD Areas in a manner that produced runoff or increased spring flow. With these measures in place, increases in sediment directly to Libby, Poorman or Ramsey creeks from tree thinning or use of the LAD Areas are not expected.

A Diversion Dam in Little Cherry Creek would be constructed to divert flow above the dam around the tailings impoundment. After the Diversion Dam was constructed during the Construction Phase, water in Little Cherry Creek above the tailings impoundment would be diverted to Libby Creek via a 10,800-foot long Diversion Channel to ensure that it would not contact any mine wastewater, waste rock or tailings. The channel would be sized to divert large flood flows safely around the tailings impoundment. The Diversion Channel would consist of an upper channel, and two existing natural drainage channels that flow toward Libby Creek. Two natural drainages would be used to convey water from the upper channel to Libby Creek. The northern drainage (Drainage 10) is currently a 9,000-foot long intermittent drainage that is primarily unchannelized in the upper part and has perennial channelized segments interspersed with unchannelized wet and dry segments in the lower part. The southern drainage (Drainage 5) is about 3,000 feet long with similar characteristics to Drainage 10. Flow in Drainage 5 does not reach Libby Creek (Kline Environmental Research 2012).

During the Construction Phase, the flow in Drainages 5 and 10 would increase and would change to perennial flow. Because the tributaries are not large enough to handle the expected flow volumes, downcutting and increased sediment delivery to Libby Creek is expected to occur as the channel stabilized. In the event of heavy precipitation during construction of the channel, substantial erosion and short-term increases in sedimentation to the lower drainage and Libby Creek would occur. Where possible, MMC would construct some bioengineered and structural features in the two drainages to reduce flow velocities, stabilize the channels, and create fish habitat. An energy dissipater would be constructed at the outlet section of both drainages to reduce flow velocity of water entering Libby Creek. Short sections of these two drainages are steep, and it may be difficult to access such sections to complete any channel stabilization work. In addition, some sections of these two drainages have thick vegetation that may require clearing before starting channel stabilization, which may temporarily create erosion and increase sediment delivery to the drainages.

The KNF's analysis of sediment erosion from roads to streams compared existing conditions (road use without the mine) to the action alternatives (Table 125). Existing sediment delivery varied by alternative because roads proposed for use in each alternative would be different. The KNF implements BMPs on roads when they are upgraded for various purposes; the analysis assumes the KNF would not upgrade any of the roads used for Alternative 2 before the Montanore Project is implemented. The KNF also assumed that BMPs would not be implemented to forest roads without the project. During the Evaluation and Construction Phases, 9.8 tons of sediment would be delivered from roads to area streams compared to a sediment delivery of 32.7 tons during 5 years without BMPs under existing conditions without the project. A reduction in sediment is anticipated in the following streams: Bear, Big Cherry, Getner, Hoodoo, Libby, Little Cherry, and Ramsey creeks (KNF 2013). A less than 1-ton increase is predicted for Poorman

Table 125. Estimated Sediment Delivery from Roads to Analysis Area Streams by Mine Phase for Mine Alternatives.

Phase	Existing Sediment Delivery from Roads to Streams (tons)†	Predicted Sediment Delivery from Roads to Streams With Project (tons)	Reduction from Existing Conditions (tons)

Total	**402.30**	**174.60**	**227.70**

†Existing sediment delivery to streams is for roads that would be used in Alternatives 2, 3, or 4.
Source: KNF 2013.

Creek. The two road closures proposed in Alternative 2 for grizzly bear mitigation would not reduce sediment reaching streams because they are not available for closure. One road proposed for closure, NFS road #4784 (upper Bear Creek Road) would be closed for mitigation of the Rock Creek Project. The other road proposed for closure, NFS road #4724 (South Fork Miller Creek), would be used in constructing transmission line Alternatives D-R and E-R.

Although MMC would implement BMPs to reduce sedimentation, MMC may request and the DEQ may authorize a short-term exemption from surface water quality standards for total suspended sediments and turbidity for construction of the powerline, access roads, the tailings impoundment, and other stream crossings. If authorized, the exemption would include conditions that minimize, to the extent practicable, the magnitude of any change in water quality and the length of time during which any change may occur. Any exemption would ensure that existing and designated beneficial uses of state water were protected and maintained upon completion of the activity.

Surface water monitoring would include regular sampling for total suspended sediments and turbidity. In all alternatives, MMC would inspect the BMPs at least once every 14 calendar days, and within 24 hours after any precipitation event of 0.5 inches or greater or within 24 hours after a snowmelt event that produced visible runoff at the construction site. MMC would maintain the BMPs so that they remained effective. Post-construction, BMPs would be inspected at least monthly (during the snow-free period) until revegetation was successful and, as during construction, within 24 hours after any precipitation event of 0.5 inches or greater or a snowmelt event that produces visible runoff. Inspection and monitoring of stormwater BMPs would continue until the areas disturbed during construction were finally stabilized. If the agencies were to observe increased suspended sediment concentrations that could not be explained by natural events such as snowmelt or large precipitation events, the agencies would investigate the source of the increased sediment load to the stream. If the agencies determined that sediment discharge was occurring to a stream from a construction or post-construction mine or transmission line site, MMC would be required, after notification from the agencies, to implement measures to eliminate the sediment source to the stream within 24 hours. These measures would eliminate or minimize erosion and sedimentation of area streams.

As part of its proposed Fisheries Mitigation Plan, MMC would conduct a sediment-source inventory in the watershed, and stabilize, recontour, and revegetate priority sediment-source areas, which are typically roadcuts in the watersheds of Libby, Hoodoo, Poorman, Midas, and Crazyman creeks. MMC's proposed mitigation is not reflected in the sediment rates shown in Table 125. Implementation of this measure would reduce the sediment delivery to area streams. MMC also would rehabilitate habitat upstream from the mouth of Howard Creek through creation of pool and hiding cover habitat, stabilization of old mining spoils, and channel narrowing. The installation of grade control structures in streams to improve aquatic habitat may increase sediment concentrations in streams temporarily. After the activities were completed, and the improvements stabilized, sediment delivery to area streams would decrease below existing levels.

3.13.4.2.2 Operations Phase (Years 6 through 25)

Groundwater

Mine Area

Groundwater in the vicinity of the adit and mine would flow toward the mine and adit voids, so groundwater quality surrounding the adits and mine would not be affected by the mine. Adit, mine, and tailings impoundment water would be collected and used for milling purposes.

Libby Adit Area

No mine or adit water would be treated at the Water Treatment Plant and discharged Creek during operations because all water would be used in the mill.

Tailings Impoundment Area

During the Operations Phase, it is estimated that a maximum of 25 gpm of water would seep to groundwater under the tailings impoundment (Klohn Crippen 2005). The existing groundwater quality would be altered because tailings seepage would have higher concentrations of nutrients, some metals, and total dissolved solids than existing groundwater.

Using the DEQ's approach for determining a standard mixing zone (ARM 17.30.517), MMC estimated a groundwater flux of 10 gpm. An additional 25 gpm was added to the estimated flux to account for flow in the buried alluvial channel (Geomatrix 2007b). The hydrologic and geologic conditions of the Little Cherry Creek Tailings Impoundment Site are complex. The agencies used a groundwater flux of 35 gpm in the agencies' mass balance calculations for Alternative 2 as a reasonable estimate of flux beneath the impoundment site. Results of the mass balance analysis are provided in Table 126. The predicted groundwater concentrations were compared to the BHES Order limits, where applicable, or applicable nondegradation criteria.

During operations, elevated antimony and manganese concentrations are predicted to occur in groundwater beneath and downgradient of the tailings impoundment. The manganese exceedance of the BHES Order limit is due in part to the ambient groundwater manganese concentration exceeding the BHES Order limit. Based on analyses of the Troy Mine decant pond disposal system by Land and Water Consulting (2004), Hydrometrics (2010) and Camp, Dresser and McKee (2010), the agencies anticipate natural attenuation and removal of metals in the tailings water infiltrated at the tailings impoundment. Assuming that geochemical conditions would be similar at Montanore as at the Troy Mine, groundwater metal concentrations beneath the impoundment area are expected to be less than those predicted by the mass balance calculations (Table 126). Nitrate would not be attenuated or removed as mine water infiltrated to groundwater.

In a 2004 study, Land and Water Consulting (2004) evaluated the fate and movement of copper beneath the Troy Mine decant ponds. Geologic material beneath the decant ponds was analyzed for total copper to identify the composition of copper minerals and to identify which mineral phases contain the most copper. Study results indicated that copper was attenuated within the upper foot of soil primarily through the precipitation of secondary copper minerals (carbonates, silicates, and oxides) and through the secondary adsorption of copper onto organic matter. Precipitation is the formation of a solid (mineral) from dissolved constituents in groundwater, and adsorption is a process where dissolved metal adheres to the surface of organic particles (USDA Forest Service and DEQ 2012).

Table 126. Predicted Concentrations in Groundwater after Mixing beneath the Tailings Impoundment without Attenuation, Alternatives 2 and 4.

Parameter	Ambient Concen-tration	Opera-tions Phase	Post-Closure at Stabilized Flow Conditions	Applicable Nondegradation Criteria Outside of a Mixing Zone			
				BHES Order Limit[1]	Ambient Concen-tration[2]	Trigger Value[3]	15% of Lowest Standard[4]
Total dissolved solids	60	146	86	100			
Nitrate, as N	<0.10	5.5	1.7	TIN=1			
Antimony-T	<0.0030	**<0.011**	**<0.0055**			0.0004	0.0009
Arsenic-C	<0.0030	<0.0025	<0.0028		<0.0030		
Barium-T	<0.040	<0.069	<0.049			0.002	0.15
Beryllium-C	<0.0010	<0.0010	<0.0010		<0.0010		
Cadmium-T	<0.00010	<0.00046	<0.00021			0.0001	0.000075
Chromium-T	<0.00074	<0.00085	<0.00077	0.005			
Copper-T	<0.0012	<0.012	<0.0043	0.003			
Iron-H	<0.010	<0.027	<0.015	0.1			
Lead-T	<0.00028	<0.0020	<0.00080			0.0001	0.0023
Manganese	<0.077	**<0.26**	**<0.13**	0.05

Selenium-T	<0.0010	<0.0011	<0.001			0.0006	0.0075
Silver-T	<0.00050	<0.0010	<0.00064			0.0002	0.015
Zinc-T	<0.0064	<0.0079	<0.0069	0.025			

All concentrations are mg/L. All metal concentrations are for dissolved metals.
Method used to derive representative ambient water quality concentrations described in ERO 2011c.
Concentrations presented with a < symbol had at least one sample with a reported concentration less than the detection limit used in calculating representative values; detection limit used in calculating representative value when reported concentration was below the detection limit.
Predicted concentrations greater than BHES Order limits or applicable nondegradation criteria without additional primary treatment before land application are shown in **bold**.
[1] BHES Order limits apply to only to those parameters for which limits were set in 1992: total dissolved solids, nitrate, chromium, copper, iron, manganese, and zinc.
[2] No increase in ambient concentrations outside of a mixing zone designated by the DEQ applies to degradation determination in nondegradation review for arsenic beryllium, and mercury.
[3] Trigger values apply to degradation determination in nondegradation review for antimony, barium, cadmium, lead, nickel, selenium, and silver.
[4] 15% of lowest standard only applies to degradation determination for concentrations of toxins (antimony, barium, cadmium, copper, lead, nickel, selenium, and silver) outside of a mixing zone designated by the DEQ if the change in water quality exceeds the trigger value.
Source: Appendix G.

The geochemical conditions at the Troy Mine tailings impoundment conducive to metals attenuation and removal included neutral to alkaline pH, oxidizing conditions, the presence of moderate amounts of dissolved silica, bicarbonate, and low to moderate amounts of organic material (Hydrometrics 2010). The metals that were attenuated or reduced at the Troy Mine tailings impoundment area included antimony, arsenic, copper, and lead. Comparing decant pond water concentrations to those collected in the adjacent downgradient groundwater at the Troy Mine, Hydrometrics (2010) reported a 50 percent reduction in antimony concentrations, an order of magnitude (10 times) reduction in copper concentrations, and reduction to undetectable concentrations for arsenic. Cadmium, mercury, and silver were not detected in either the Troy

Mine decant pond water or the underlying shallow groundwater. Based on scientific literature, Hydrometrics (2010) concluded that if higher concentrations of cadmium, mercury, or silver occurred in the decant pond water, the necessary geochemical conditions existed to attenuate and remove these metals.

Camp Dresser and McKee (2010) completed a study of the Troy Mine decant ponds for the DEQ designed to evaluate whether other attenuation or removal mechanisms of metals that would occur in the event that the initial mechanisms, such as precipitation, became less effective. These secondary attenuation processes would occur when oxygen-rich mine water from the decant ponds mixed with groundwater. When oxygen-poor groundwater contains iron, dissolved iron precipitates from solution as iron hydroxide (a solid mineral). When the iron hydroxide precipitates, it facilitates removal of other metals from water by co-precipitation. Specifically, the 2010 Camp, Dresser and McKee study evaluated the following: whether dissolved iron in groundwater would precipitate as iron hydroxide; whether dissolved iron that precipitates would help remove copper and other metals (co-precipitation) from mine waters; and the quantity of other metals that would be removed with the iron. The evaluation consisted of computer geochemical modeling based on the quality of mine water and the groundwater under the tailings impoundment; and bench-scale jar testing using varying proportions of mine water and groundwater. The computer modeling showed that between 98 and 100 percent of the iron would precipitate in response to mixing of the waters, while the laboratory tests showed that precipitation of the iron resulted in the removal of 73 to 98 percent of the copper and 11 to 59 percent of the antimony (Camp Dresser and McKee 2010).

Based on the mass balance calculations, seepage of impoundment water is predicted to increase the manganese concentration in groundwater under the tailings impoundment. Oxygenation of the water stored as surface water in the impoundment would cause the precipitation of manganese oxide and a decrease in the dissolved manganese concentration in the impounded water. Therefore, the predicted manganese groundwater concentration based on the mass balance calculation may be higher than would actually occur. The predicted manganese concentration exceeds the BHES Order limit. Although the manganese concentration may exceed the BHES Order limit beneath the impoundment, all groundwater containing elevated concentrations would be intercepted by the pumpback wells and returned to the mill or treated and discharged. The pumpback well system would minimize the effect to groundwater quality and prevent the movement of the tailings seepage water to any surface water.

In all mine alternatives, a MPDES-permitted outfall would not be required for the tailings impoundment seepage because seepage reaching groundwater would be collected by the pumpback system and not discharged to surface water. The discharge to groundwater beneath the impoundment would be authorized by a DEQ Operating Permit and a seepage recovery zone would encompass the impoundment footprint and extend to the pumpback wells, if installed. MMC requested a source-specific groundwater mixing zone for the tailings impoundment in Alternative 2 (Geomatrix 2007b). The DEQ would make the same determinations regarding a mixing zone as it would for discharges at the LAD Areas.

LAD Areas

Groundwater quality beneath the LAD Areas would not be affected because discharge to the LAD Areas would not occur during operations.

Surface Water

West Side Streams, Lakes, and Springs

Mine dewatering and the resulting drawdown of bedrock groundwater may subtly change the water quality of various water bodies, such as the East Fork Rock Creek, Rock Lake, East Fork Bull River, and springs and seeps. Reducing the source of deeper groundwater may reduce the concentration of some anions and cations in surface water, such as sodium, calcium, potassium, bicarbonate, magnesium, chloride, and sulfate. If such a water quality change occurred, it would be detectable only during low flow periods when bedrock groundwater is the major source of supply to surface water. Even at low flows, the changes in water quality may be difficult to measure.

Maximum modeled nitrogen emissions from the exhaust adit at the Libby Adit Site during operations in Alternative 2 are predicted to exceed deposition analysis thresholds at Upper Libby Lake, Lower Libby Lake and Rock Lake. Maximum sulfur deposition impacts were less than the deposition analysis thresholds at Lower Libby Lake and Rock Lake and greater than the deposition thresholds at Upper Libby Lake (see Table 56, p. 297). Upper Libby Lake with very low ANC values would be at risk of becoming more acidic in Alternative 2.

East Side Streams, Lakes, and Springs

Mine Dewatering and Discharges. The effects on streams, springs, and seeps due to mine dewatering would be the same as described for west side surface water. No lakes in the Libby Creek watershed would be affected by mine dewatering. Discharges of mine, adit and tailings impoundment water from the LAD Areas and the Water Treatment Plant during operations were not proposed because the water would be used for milling purposes. If sustained inflows higher than those predicted by the 3D model occurred during the Operations Phase, MMC would implement excess water contingency actions, such as increased grouting, increased sprinkler evaporation at the impoundment, increased storage in the impoundment, or, if necessary, treatment and discharge at the Water Treatment Plant. Discharges would likely be less than the rates during the Construction, Closure and Post-Closure Phases, and water quality effects would be less than predicted for those phases.

The pumpback wells downslope of the Little Cherry Creek tailings impoundment would reduce streamflow in Libby, Little Cherry and likely Bear creeks. The pumpback well system would likely eliminate the $7Q_{10}$ flow in the diverted Little Cherry Creek and substantially reduce the $7Q_2$ flow. Flow below the Seepage Collection Dam in the former Little Cherry Creek channel would also be substantially reduced. Shallow groundwater at the impoundment site has higher total dissolved solids, nitrate, and metal concentrations than Libby Creek. The flow reduction in Libby Creek and Bear Creek would be less than 10 percent of the estimated $7Q_{10}$ flow. It is likely that changes in the water quality of Libby Creek and Bear Creek during operation of the pumpback wells would not be detectable.

Effects of Runoff from Roads. The KNF's WEPP analysis found that roads proposed for use by Alternative 2, with BMPs, would deliver and estimated 69 tons of sediment that would reach area streams during the Operations Phase, a reduction of 61.6 tons from existing conditions (Table 125) (KNF 2013). BMPs and monitoring would be implemented to minimize sediment reaching streams. Road closures proposed in Alternative 2 would not reduce sediment reaching streams.

As part of MMC's Fisheries Mitigation Plan (see section 2.4.6.2, *Fisheries*), MMC may conduct a sediment-source inventory in the watershed, and stabilize, recontour, and revegetate priority source areas, which are typically roadcuts in Libby, Hoodoo, Poorman, Midas, and Crazyman creeks. If selected as part of the Fisheries Mitigation Plan, these measures would reduce sediment to area streams.

Risks of Impoundment Failure during Construction, Operations, and Closure. The agencies evaluated the risks associated with impoundment failure during construction, operations, and closure using a failure modes effects analysis (Klohn Crippen Berger 2009). The analysis identified potential failure modes of all project components. For each failure mode, the agencies estimated the likelihood of occurrence and likely consequences to determine an overall risk level. The risk level integrated likelihood and consequences. The analysis included a discussion of risk management plans.

The assessment evaluated the main dam, the impoundment and associated facilities, tailings and water transport, and closure. Most of the risks associated with impoundment construction, operations, and closure were low or inconsequential. The assessment identified three failure modes for the Little Cherry Creek impoundment with moderately low risks that had the potential to cause water quality effects. The effect of these failure modes would adversely affect groundwater quality beneath the impoundment or surface water in former Little Cherry Creek or Libby Creek.

The failure mode with the highest consequence was failure of the tailings dam due to the liquefaction of the loose glacial outwash layer beneath the tailings impoundment under seismic loading (result of an earthquake). The likelihood of liquefaction of the glacial outwash layer is discussed in section 3.14.3 of the *Geotechnical* section. Should such a failure occur, sediment, tailings, and impoundment water would be uncontrollably released to the environment. The volume of material released and the effect of the release on the environment cannot be predicted, and would depend on many factors, including the type of failure, size of the tailings impoundment at the time of failure, volume of water associated with the failure, and the initial volume and character of the sediments, and the character of concurrent releases from other sources. Under the worst-case scenario, tailings impoundment water containing dissolved metals and reagent residues, and large masses of tailings and sediment would flow into the Libby Creek stream channel. Some of the material would probably remain in the channel for an undefined period of time following failure, while the liquid and remaining solids would be carried downstream. Water quality would be substantially affected. Subsequent to any such failure, seasonal high flows would continue to wash most of the remaining material downstream. Most of the fine sediment from any such catastrophic failure would probably persist in the Libby Creek watershed for many years.

Another potential risk is the release of tailings from a tailings pipeline leak. For example, at the Troy Mine, a recent failure released about 45 tons of tailings into a nearby creek. Suspended sediments were briefly observed for more than 14 miles downstream to the Kootenai River. The failure was caused by a 2-centimeter hole in tailings pipeline. This section of pipe now is equipped with a secondary containment structure. The Troy mine pipeline is polymer lined single-walled pipe buried over much of its length, with a pressure-sensitive leak detection system. The line has some secondary containment at its midpoint, and some secondary containment at stream crossings. In Montanore, the greatest risk would be at the crossings of Ramsey Creek and Poorman Creek. The pipelines would not be buried at the Ramsey Creek or Poorman Creek crossings, but would be in a lined, covered trestle adjacent to the bridge. The creek crossings would have secondary containment built into the crossings besides the double-walled pipe. The containment would be covered and drain toward a designed sump or tank system. Valves would be installed on either side of the crossings to minimize the quantity of tailings that would reach the creek. Should the tailings reach a creek, water quality would be substantially affected. Subsequent to any such failure, seasonal high flows would wash most of the remaining material downstream. Most of the fine sediment from any such failure would probably persist in the Libby Creek watershed for many years.

Risk of Accidental Spills and Ruptures. In all alternatives, MMC would use non-hazardous and small amounts of hazardous materials in its operations, including reagents during milling (potassium amyl xanthate, methyl isobutyl carbinol and polyacrylamide), lubricants, fuel, and blasting agents. Material safety data sheets for the proposed reagents are presented in MMC's Plan of Operations (MMI 2005a, MMC 2008).

The agencies evaluated the risk associated with several possible accidental spill failure modes, such as loss of fuel at the plant site from equipment failure or operator error, spills of materials along access roads from accidents or operator error, and spills of concentrate between the plant site and Libby Loadout (Klohn Crippen Berger 2009). A spill or release may result in short-term water quality degradation of area streams. The effect would depend on the response time for cleanup, the toxicity of the material spilled, the size of the spill, how much entered the creek, and how much dilution occurred within the stream. The risk level for the evaluated accidental spill failure modes was low or inconsequential (Klohn Crippen Berger 2009). MMC would implement an Emergency Spill Response Plan in the event of any spill or release.

A rupture or break in either the proposed tailings slurry or return water pipelines may result in short-term water quality degradation. All pipelines would be encased in larger pipes at stream crossings, and emergency storage areas would be provided in critical reaches along the utility corridor. Slurry lines would be continuously operated and monitored at the ore concentrator at the mill. In the event that pipeline leakage occurred, the system would be shut down and immediately repaired. Impacts for major ruptures would depend on the location of the rupture and the response time for cleanup. The agencies evaluated the risk associated with tailings slurry or return water pipelines. Based on the proposed pipeline design, the risk level associated with failure of tailings slurry or return water pipelines leading to the Little Cherry Creek impoundment was low (Klohn Crippen Berger 2009).

3.13.4.2.3 Closure and Post-Closure Phases (Years 25+)

Groundwater

Mine Area

During the Closure Phase in Alternative 2, the adits would be plugged at the surface, and groundwater would begin to fill the mine and adit void. The 3D model predicted that the mine void and adits would require about 490 years to fill. Groundwater in the vicinity of the mine would continue to flow toward the mine void until the regional potentiometric surface recovered to near pre-mining conditions after a predicted 1,150 to 1,300 years after mining ended. The actual time to recover to steady state may be shorter or longer based on actual adit and mine inflow rates and adit plug locations, and would be re-evaluated using the 3D model after additional data were collected during the Evaluation Phase. Groundwater quality would not be affected during the Closure Phase.

For adits from which water may discharge after mine closure, a water-retaining plug would be installed in competent bedrock. Design of the water-retaining plug would be determined by hydrologic and geotechnical data. Because water-retaining plugs can be located deeper into the adit than a dry plug, the adits from the portal to the plug would be backfilled. Final plugging design for “wet” openings would be prepared for the agencies’ approval before cessation of operations.

The agencies anticipate the quality of the post-closure mine water would be similar to the Troy Mine water quality when it was not operating (Appendix K-8). The potentiometric surface would begin to recover, but water would continue to flow toward the mine void for hundreds of years. Eventually, water may begin to flow out of the mine void, mix with groundwater in saturated fractures, react with iron oxide and clay minerals along an estimated 0.5-mile or greater flow path, undergo changes in chemistry due to sorption of trace elements and mineral precipitation, and, without mitigation, and flow at a predicted rate of 0.07 cfs (32 gpm) as baseflow to the East Fork Bull River. Using all available hydrologic data collected during mining, mitigation (low permeability barriers in the mine) would be designed to minimize post-mining streamflow changes in the East Fork Rock Creek and East Fork Bull River.

Tailings Impoundment Area

During the Closure Phase, the tailings would continue to consolidate and MMC would begin reclamation of the impoundment. MMC estimates it would take up to 20 years for settling and consolidation at the tailings impoundment to stop and to completely reclaim the tailings impoundment surface. MMC would continue to operate the seepage collection system and pumpback wells until BHES Order limits or applicable nondegradation criteria were met without treatment. As adjacent compliance wells met applicable standards, individual pumpback wells may be shut down and adjacent compliance wells would continue to be monitored. As a result, long-term water treatment and surface water and groundwater quality monitoring may be required. The Water Treatment Plant and LAD Areas would continue to be used for treatment of water collected by the seepage collection and pumpback well systems. Effects on groundwater quality would be similar to the Operations Phase.

Seepage from the tailings impoundment reaching groundwater is estimated to decrease from 25 gpm to 17 gpm about 10 years after closure, stabilizing at 5 gpm at steady state conditions (Klohn Crippen 2005). The effect on groundwater quality under the tailings impoundment at a seepage rate of 25 gpm during operations and 5 gpm when the seepage rate is estimated to stabilize is provided in Table 126. Water quality effects during the Closure and Post-Closure Phases when the seepage rate would be decreasing, before stabilizing at 5 gpm, would be less than shown for operations and greater than shown for steady state conditions. The analysis predicted that the water quality standard for antimony and the BHES Order limit for manganese would be exceeded at both the 25 gpm and 5 gpm seepage rates. The manganese exceedance of the BHES Order limit is due in part to the ambient groundwater manganese concentration exceeding the BHES limit. As discussed under the Operations Phase, the predicted antimony and manganese groundwater concentrations based on the mass balance calculation may be higher than would actually occur because of attenuation. Water quality beneath the impoundment would improve slowly over time as infiltrated precipitation mixed with water retained in the impoundment, and water quality concentrations in groundwater after mixing beneath the tailings impoundment would be less than shown in Table 126. MMC would maintain and operate the necessary seepage collection facilities (underdrain system and pumpback wells) until BHES Order limits or applicable nondegradation criteria were met, without treatment, in all receiving waters. MMC also would continue water monitoring as long as the MPDES permit was in effect. As long as post-closure water treatment was required, the agencies would require a bond for the operation and maintenance of the water treatment facilities. The length of time these closure activities would occur is not known and may be decades or more.

LAD Areas

The projected effects on groundwater under the LAD Areas after mill operations ceased are provided in Table 121. Total dissolved solids, nitrate, and dissolved antimony, arsenic, barium, beryllium, cadmium, and manganese concentrations are predicted to exceed one of the applicable criteria. The manganese exceedance of the BHES Order limit is due in part to the ambient groundwater manganese concentration exceeding the BHES Order limit. The predicted dissolved metal concentrations may be higher than would actually occur because they may be attenuated or removed. As infiltrated precipitation mixed with water in the tailings impoundment, the quality of collected tailings seepage water sent to the LAD areas would improve, and the concentrations beneath the LAD Areas would be less than those shown in Table 122, Table 123, and Table 124. The length of time tailings water may be discharged at the LAD Areas is not known and may be decades or more. Water quality beneath the LAD Areas would return to pre-mine conditions soon after discharges to the areas ceased.

Libby Adit Area

Water treated at the Water Treatment Plant (up to 500 gpm in Alternative 2) may be discharged to groundwater via a percolation pond located in the alluvial adjacent to Libby Creek. The expected quality of the treated water would be below groundwater BHES Order limits and nondegradation criteria. The length of time water may be discharged from the Water Treatment Plant is not known and may be decades or more. Groundwater quality would return to pre-mine conditions soon after discharges to the percolation pond ceased.

Surface Water

West Side Streams, Lakes, and Springs

Effects on west side streams, lakes, and springs would persist through the Closure and Post-Closure Phases as mine dewatering would continue to reduce the potentiometric surface. Without mitigation, the largest reductions in deep bedrock groundwater discharge to springs, the East Fork Rock Creek, Rock Lake, and East Fork Bull River would occur about 16 years after mine closure. After that time, groundwater discharges to surface would begin to increase as the potentiometric surface was recovering. Reduced bedrock groundwater entering surface water may reduce the concentration of some anions and cations in surface water, such as sodium, calcium, potassium, bicarbonate, magnesium, chloride, and sulfate. Whether water quality changes would be detectable or could be separated from natural variability is unknown. Based on previous studies of Rock Lake (Gurrieri 2001, Gurrieri and Furniss 2004), the water quality in Rock Lake may change due to the reduction in deep bedrock groundwater, and may be detectable if mitigation to reduce effects on Rock Lake were not implemented. The lake could become somewhat more acidic, could lose some of its buffering capacity, and the loads of nutrients (especially nitrate), sulfate, calcium, magnesium, sodium, and silicon dioxide could be reduced. These changes could reduce nutrient availability to phytoplankton in Rock Lake.

If mine void water flowed to the East Fork Bull River after mine closure, it is not likely that changes in water quality in the river would be detectable. The effect cannot be accurately quantified without additional information from the underground mine. To develop a quantitative estimate of the actual effect, MMC would monitor the chemistry within the underground workings, evaluate downgradient groundwater flow and chemistry within bedrock fracture systems, and monitor baseflow in the East Fork Bull River (see Appendix C, *Water Resources Monitoring*).

Nitrogen and sulfur emissions from the mine's exhaust adit at the Libby Adit Site would substantially decrease when underground mining ceased and would end when all underground mobile equipment ceased operating.

East Side Streams, Lakes, and Springs

Water Quality. Without mitigation, the largest reductions in deep bedrock groundwater discharge to springs and streams in the Libby Creek watershed would occur about 3 years after mine closure. Reduced bedrock groundwater entering surface water may reduce the concentration of some anions and cations in surface water, such as sodium, calcium, potassium, bicarbonate, magnesium, chloride, and sulfate. Whether water quality changes in Libby Creek above the Water Treatment Plant discharge point or in Ramsey Creek would be detectable or could be separated from natural variability is unknown. After mine closure and plugging of the adits near the surface, groundwater contributions to surface water would begin to increase as the potentiometric surface was recovering. After the adit filled, baseflow conditions would return to pre-mining conditions, and stream water quality is not expected to be affected. No lakes in the Libby Creek watershed would be affected by mine dewatering or changes in the potentiometric surface after mining.

Discharges from the LAD Areas are predicted to exceed BHES Order limits or applicable nondegradation criteria for six metals in Ramsey Creek, five metals in Poorman Creek, and three metals in Libby Creek (Table 122, Table 123, and Table 124). Libby Creek is listed by DEQ as impaired for drinking water use due to exceedances by mercury of the human health standard; the mercury concentration in discharges would be below the human health water standard. In 2014, the DEQ and EPA issued TMDLs and a water quality improvement plan for the Kootenai River-Fisher River project area, which includes Libby Creek. The DEQ performed updated assessments on Libby Creek for metals impairment and did not identify metals impairment conditions in Libby Creek in the reassessment (DEQ and Environmental Protection Agency 2014). The impairment causes for this 1 mile section of Libby Creek (mercury) will be removed from the 2014 Water Quality Integrated Report.

After the impoundment was reclaimed and runoff met BHES Order limits or applicable nondegradation criteria, runoff from the reclaimed tailings impoundment surface and the watershed west of the impoundment would be routed toward Bear Creek. The water quality of Bear Creek would not be degraded by the runoff. MMC would design a riprapped channel to Bear Creek. The design would incorporate features that provide for stability of a transition zone so that sediment delivery to streams was not increased. A small, rock-filled check dam would be located just beyond the northwest end of the reclaimed impoundment. The check dam would be designed for the 100-year storm event. Sediment would be removed from behind the dam, if necessary. These measures would minimize the amount of sediment reaching Bear Creek. Increased sedimentation to Libby Creek within the upper and lower impaired segments would likely not occur.

The KNF's WEPP analysis found that roads proposed for use by Alternative 2, with BMPs, 25.6 ton of sediment would reach area streams during the Closure and Post-Closure Phases, a reduction of 7.2 tons compared to existing conditions for the same roads without BMPs (Table 125) (KNF 2013). BMPs and monitoring would be implemented to minimize sediment reaching streams. Road closure mitigation would not affect sediment generation during the Closure Phase. In the event that a large runoff-producing storm occurred during the initial reclamation period, soil losses along roads and road cuts may be locally moderate to severe.

3.13.4.2.4 Climate Change

It is difficult to predict how the hydrologic systems in the analysis area would respond to the forecasted regional effects of climate change. Decreased groundwater contribution to baseflow in streams and groundwater flow to wilderness lakes could change the chemistry of the streams and lakes, as could a seasonally altered runoff pattern. If climate change reduced groundwater infiltration enough to reduce mine and adit inflows, less water would contact exposed mineralized rock, which could reduce metal mobility and the potential for metal leaching in the mine. Discharges of treated water to Libby Creek would be less if mine and adit inflows decreased. Any effect on water quality from the project, combined with the effects of climate change, may be different than those estimated to occur with the Montanore Project alone. As described in Appendix C, MMC would monitor streamflows and water temperatures at potential impact area sites and benchmark sites (similar to project area sites, but outside the area of potential mine impacts) to evaluate trends due to mining compared to trends due to non-mining effects such as climate change. For all discharges, the DEQ would determine effluent limits for each outfall that were protective of aquatic life during the MPDES permitting.

3.13.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Alternative 3 would incorporate modifications and mitigating measures proposed by the agencies that would reduce water quality impacts on area streams and springs. The LAD Areas would not be used in Alternative 3. Any excess water would be treated at the Water Treatment Plant at the Libby Adit Site and discharged at existing permitted outfalls. The tailings impoundment would be at the Poorman Impoundment Site, which would not require diversion of Little Cherry Creek. Seepage from the Poorman Tailings Impoundment Site would be intercepted by pumpback well system during the Operations, Closure and Post-Closure Phases. Power backup would ensure that the pumpback wells would be continuously operated to protect surface water and groundwater quality. During system maintenance, individual pumps would be shut off for only short periods of time to maintain complete capture around the tailings impoundment. Tailings and reclaimed water pipelines would be buried, which, along with a leak detection system, would reduce the risk of affecting surface water resources. Sanitary waste would be treated on-site and pumped to the tailings impoundment during operations. MMC would comply with Forest Service policies when disposing of demolition debris during Closure. The total disturbance area for Alternative 3 would be 1,565 acres. The following sections discuss only those effects that would be different from Alternative 2.

3.13.4.3.1 Effects of Mine Inflows and Pumpback Wells

The effects from mine inflows on surface water and groundwater quality during the Evaluation through Operations Phases would be the same as described for Alternative 2. The effect on water quality in streams, springs, and lakes during the Closure and Post-Closure Phases would be less than Alternative 2 due to implementing mitigation measures to reduce effects on water quality. Depending on the relative contribution of surface water, shallow groundwater and deep groundwater to each surface water and groundwater body, water quality changes may be slight and not detectable, or may be greater and detectable. Because the Ramsey Adits would not be constructed, Ramsey Creek would be affected less than in Alternative 2 because there would be less drawdown in the Ramsey Creek watershed due to mine inflows. Three adits in the Libby Creek drainage would reduce streamflow in Libby Creek slightly more than Alternative 2, so water quality effects on upper Libby Creek (above the Water Treatment Plant point of discharge) may be slightly greater than in Alternative 2.

The pumpback wells, located downgradient of the tailings impoundment (Figure 26), would reduce streamflow in Poorman and Libby creeks. The modeled flow reduction in Poorman Creek would be up to 9 percent of the estimated $7Q_{10}$ flow. Shallow groundwater at the impoundment site has higher total dissolved solids, nitrate, and metal concentrations than Poorman and Libby creeks. During low flows, reducing shallow groundwater contribution to the creek may result in slight detectable changes in the water quality of Poorman Creek. It may not be possible to separate such changes from natural variability. In Libby Creek, the flow reduction due to pumping from the pumpback wells would be less than 10 percent of the estimated $7Q_{10}$ flow; it is likely that changes in the water quality of Libby Creek during operation of the pumpback wells would not be detectable.

Rock Creek is listed by the DEQ as impaired due to anthropogenic substrate alterations, with the probable source of impairment listed as silvicultural activities. The DEQ issued a sediment TMDL for Rock Creek (DEQ 2010a). It is unlikely that the predicted flow decreases in the East Fork Rock Creek (up to 0.29 cfs at EFRC-200) and Rock Creek (up to 0.65 cfs at RC-2000), which are small compared to channel-forming flows, would affect sediment transport, aggradation and degradation in East Fork Rock Creek or Rock Creek.

3.13.4.3.2 Effects of Discharges

During all mine phases in Alternative 3, excess water would be treated at the Water Treatment Plant and discharged to an outfall at the Libby Adit Site. The existing treatment plant would be modified to treat nitrogen compounds (primarily nitrates and ammonia), phosphorus, and possibly dissolved metals, and its capacity increased. An additional outfall may be needed in Ramsey Creek to avoid adversely affecting senior water rights. The pH of the discharge of mine and adit water is expected to be about 8, slightly greater than in-stream pH values of between 6.5 and 7.5 in Libby Creek. Water discharged from the Water Treatment Plant, if discharged to the percolation pond next to Libby Creek, would mix with groundwater with a pH of about 6.5. Mixing would also occur within an authorized mixing zone in Libby Creek. After mixing, water treated and discharged from the Water Treatment Plant would be below BHES Order limits and applicable nondegradation criteria in surface water and groundwater. Groundwater and surface water quality would not be adversely affected.

Libby Creek is listed by the DEQ as impaired for drinking water use due to exceedances by mercury of the human health standard; the mercury concentration in receiving waters after mixing would be below the human health standard. In 2014, the DEQ and EPA issued TMDLs and a water quality improvement plan for the Kootenai River-Fisher River project area, which includes Libby Creek. The DEQ performed updated assessments on Libby Creek for metals impairment and did not identify metals impairment conditions in Libby Creek in the reassessment (DEQ and Environmental Protection Agency 2014). The impairment cause for this 1 mile section of Libby Creek (mercury) will be removed from the 2014 Water Quality Integrated Report.

Libby Creek is also listed as impaired for aquatic life use due to alterations in physical substrate habitat, sediment and siltation. The increase in flow from the Water Treatment Plant would be negligible during high flows, and is predicted to increase low flow by more than 100 percent of the modeled baseflow at LB-300 during operations (from 1.2 to 3.1 cfs). The increase during bankfull or channel-forming flows would be less than 1 percent. The flow increase would not move substantially more material in the channel, would not alter the physical substrate habitat, and would not affect sediment transport, aggradation and degradation. To address the sediment TMDL on Libby Creek, MMC would implement BMPs included in the MPDES permit to meet the sediment wasteload allocation of 24 tons/year developed by DEQ for the project.

The mass balance analysis, using $7Q_{10}$ flow less any predicted mine inflow or pumpback well streamflow reductions, was completed for all alternatives assuming certain treated total dissolved solids, nitrogen and metal concentrations at the Water Treatment Plant outfall needed to meet applicable BHES Order limits or prevent significant changes in water quality for nutrients and toxic, carcinogenic or bioconcentrating parameters not listed in the BHES Order at all locations downstream of the Water Treatment Plant discharge mixing zone (currently LB-300). The expected water quality of the mine wastewater, adit wastewater during construction and post-construction, tailings wastewater post-operations, and Water Treatment Plant treated water quality are provided in Table 120. The discharges to Libby Creek may increase concentrations of total dissolved solids, nitrogen, phosphorus, and some metal concentrations in Libby Creek below LB-300 above ambient concentrations. Table 127 provides the results after mixing at LB-300 and Table 128 provides the results after mixing at LB-1000; results for LB-2000 are provided in Appendix G. Predicted concentrations during the Post-Closure Phase would be slightly better than those shown in the Closure Phase at LB-300 and LB-1000. Although concentrations of some parameters are predicted to increase, BHES Order limits or applicable nondegradation criteria would not be exceeded during all mine phases at either location. Poorman Creek would not be affected by discharges. Discharges would not occur to Ramsey Creek unless required for water rights mitigation; if needed, the discharged water would meet BHES Order limits and applicable nondegradation criteria. During the permitting process, the DEQ would make the same determinations regarding a mixing zone at the tailings impoundment for seepage reaching groundwater in Alternative 3 that were discussed in Alternative 2.

Total nitrogen concentrations are predicted to increase to as much as 0.96 mg/L at LB-300, 0.35 mg/L at LB-1000, and 0.38 mg/L at LB-2000, which are above the total nitrogen standard of 0.275 mg/L. Predicted increased total phosphorus concentrations would remain below the total phosphorus standard. The predicted total nitrogen increases to above the standard may result in increased levels of filamentous algae in Libby Creek below the water treatment plant discharge point. This may result in decreases in dissolved oxygen concentrations to below the standard during low flow periods in early fall, and may also result in higher pH levels in the creek. It is uncertain whether the pH standard would be exceeded due other factors that affect pH, such as chemical buffering or re-aeration rates in Libby Creek (Suplee, pers. comm. 2014).

Table 127. Predicted Concentrations after Mixing at LB-300, Alternative 3.

Parameter	Ambient Concentration	Construction Phase	Operations Phase	Closure Phase	BHES Order Limit[1]	Applicable Nondegradation Criteria Outside of a Mixing Zone			
						Ambient Concen-tration[2]	Trigger Value[3]	15% of Lowest Standard[4]	10%/40% of Lowest Standard[5]
Total dissolved solids	<25	<68	<82	<71	100				
Ammonia, as N	<0.050	<0.38	<0.49	<0.40	TIN=1				
Nitrate, as N	<0.13	<0.37	<0.45	<0.38	TIN=1				
Total inorganic nitrogen	<0.18	<0.75	<0.94	<0.78	1				
Total nitrogen	<0.26	<0.79	<0.96	<0.82					0.1/0.4
Total phosphorus	<0.0064	<0.0082	<0.0088	<0.0083					0.1/0.4

Assumed quality of Water Treatment Plant effluent discharge is provided in Table 120.
All concentrations are mg/L. All metal concentrations are for total recoverable metals except aluminum, which is dissolved.
Method used to derive representative ambient water quality concentrations described in ERO 2011c.
Concentrations presented with a < symbol had at least one sample with a reported concentration less than the detection limit used in calculating representative values; detection limits used in calculating representative values when reported concentrations were below the detection limit.
Predicted concentrations greater than BHES Order limits or applicable nondegradation criteria are shown in **bold**; no exceedances of BHES Order limits or nondegradation criteria during any mine phase were predicted.
[1] BHES Order limits apply to only to those parameters for which limits were set in 1992: total dissolved solids, nitrate, chromium, copper, iron, manganese, and zinc.
[2] No increase in ambient concentrations outside of a mixing zone designated by the DEQ applies to degradation determination in nondegradation review for arsenic, beryllium, and mercury.
[3] Trigger values apply to degradation determination in nondegradation review for aluminum, antimony, barium, cadmium, copper, lead, nickel, selenium and silver.
[4] 15% of lowest standard only applies to degradation determination for concentrations of toxins (aluminum, antimony, barium, cadmium, copper, lead, nickel, selenium, and silver) outside of a mixing zone designated by the DEQ if the change in water quality exceeds the trigger value.
[5] 10% and 40% of lowest standard applies to degradation determination review for iron, total nitrogen and total phosphorus. For total nitrogen, it was assumed that the BHES Order limit of 1 mg/L for TIN would be the applicable limit for total nitrogen. For total phosphorus, it was assumed the circular DEQ-12B variance concentration of 1 mg/L would apply.

Assumed quality of Water Treatment Plant effluent discharge is provided in Table 120.
All concentrations are mg/L. All metal concentrations are for total recoverable metals except for aluminum, which is dissolved.
Method used to derive representative ambient water quality concentrations described in ERO 2011c.
Concentrations presented with a < symbol had at least one sample with a reported concentration less than the detection limit used in calculating representative values; detection limits used in calculating representative values when reported concentration were below the detection limit.
Predicted concentrations greater than BHES Order limits or applicable nondegradation criteria are shown in **bold**; no exceedances of BHES Order limits or nondegradation criteria during any mine phase were predicted.
[1] BHES Order limits apply to only to those parameters for which limits were set in 1992: total dissolved solids, nitrate, chromium, copper, iron, manganese, and zinc.
[2] No increase in ambient concentrations outside of a mixing zone designated by the DEQ applies to degradation determination in nondegradation review for arsenic, beryllium, and mercury.
[3] Trigger values apply to degradation determination in nondegradation review for aluminum, antimony, barium, cadmium, copper, lead, nickel, selenium, and silver.
[4] 15% of lowest standard only applies to degradation determination for concentrations of toxins (aluminum, antimony, barium, cadmium, copper, lead, nickel, selenium, and silver) outside of a mixing zone designated by the DEQ if the change in water quality exceeds the trigger value.
[5] 10% and 40% of lowest standard applies to degradation determination review for iron, total nitrogen and total phosphorus. For total nitrogen, it was assumed that the BHES Order limit of 1 mg/L for TIN would be the applicable limit for total nitrogen. For total phosphorus, it was assumed the circular DEQ-12B variance concentration of 1 mg/L would apply.
Source: Appendix G.

Metals, nitrogen and total dissolved solids concentrations in groundwater after mixing beneath the Poorman Tailings Impoundment Site would be similar to Alternative 2 (Table 126), but the estimated groundwater flux under the Alternative 3 impoundment is slightly greater (41 gpm), resulting in slightly lower projected final mixing concentrations in groundwater under the tailings impoundment (Table 129). As discussed in Alternative 2, groundwater metal concentrations beneath the impoundment area during the Operations Phase may be less than those predicted by the mass balance calculations. Because water quality beneath the impoundment would improve slowly over time as infiltrated precipitation mixed with water retained in the impoundment, water quality concentrations post-closure when the seepage rate stabilized would be less than shown in Table 129.

The risk associated with ore in underground workings and waste rock and ore stockpiles in Alternative 3 would be the same as in Alternative 2. Alternative 3 might have some difference in the potential for acid rock drainage or trace element release from the construction of adits in Libby Creek instead of Ramsey Creek, as compared to Alternative 2. Minor differences in the relative volumes of waste rock lithologies intercepted in the alternative adit locations that would be developed under Alternative 3 may alter the overall potential for changes in water quality, depending upon the relative volume of Prichard and Revett formation altered waste zones to be mined. Any change would likely be minor. Characteristics and suitability of waste rock would be identified through sampling and analysis during the Evaluation Phase. The chemistry of tailings and waste rock used for impoundment construction would not change as a result of constructing impoundments in alternative locations.

The volume of waste rock to be mined from each altered waste zone, and the area of the underground workings that would expose the altered waste zone, are not yet fully defined because final mine plans would depend upon results of the proposed Evaluation Phase work. As noted above, the potential for trace metal release from waste rock used in construction or placed in stockpiles would primarily be a function of how much waste rock was mined from the reactive portions of the lower Revett Formation altered waste zones and the Prichard Formation, and how much metal those rock types would release. The zonation patterns do not indicate a higher potential for acid generation and metal leaching at the Montanore Project than that observed at the Troy Mine, but suggest the need for sampling at a level sufficient to represent the observed variability. These relationships would be further defined during the Evaluation Phase, when waste rock in these zones would be sampled more comprehensively, and would be used to support the need for further testing. Ore collected during the Evaluation Phase would be used to conduct further metallurgical testing with a goal of obtaining tailings reject for kinetic and metal mobility test work using a comprehensive suite of elements. Additional testing would be needed to support the results of a single kinetic test of tailings reported to date, and to provide a more comprehensive suite of metal mobility data for evaluating tailings impoundment performance.

The plant would be constructed at the Libby Plant Site between Libby and Ramsey creeks. Based on preliminary design, the Libby Plant Site would not be built with waste rock. If waste rock was not used to build the plant site, ELGs would not apply to the runoff, and runoff would be considered stormwater and subject to stormwater discharge requirements.

Table 129. Predicted Concentrations in Groundwater after Mixing beneath the Tailings Impoundment without Attenuation, Alternative 3.

Parameter	Ambient Concen-tration	Opera-tions Phase	Post-Closure at Stabilized Seepage Rate	Applicable Nondegradation Criteria Outside of a Mixing Zone			
				BHES Order Limit[1]	Ambient Concen-tration[2]	Trigger Value[3]	15% of Lowest Standard[4]
Total dissolved solids	60	138	82	100			
Nitrate, as N	<0.10	5.0	1.5	TIN=1			
Antimony-T	<0.0030	**<0.011**	**<0.0052**			0.0004	0.0009
Arsenic-C	<0.0030	<0.0025	<0.0029		<0.0030		
Barium-T	<0.040	<0.066	<0.048			0.002	0.15
Beryllium-C	<0.0010	<0.001	<0.001		<0.0010		
Cadmium-T	<0.00010	<0.00043	<0.00019			0.0001	0.000075
Chromium-T	<0.00074	<0.00084	<0.00077	0.005			
Copper-T	<0.0012	<0.011	<0.0039	0.003			
Iron-H	<0.010	<0.025	<0.014	0.1			
Lead-T	<0.00028	<0.0018	<0.00073			0.0001	0.0023
Manganese	<0.077	**<0.24**	**<0.12**	0.05			
Mercury-T	<0.000030	<0.000021	<0.000027		<0.000030		
Nickel-T	<0.010	<0.010	<0.010			0.0005	0.015
Selenium-T	<0.0010	<0.0011	<0.0010			0.0006	0.0075
Silver-T	<0.00050	<0.00095	<0.00063			0.0002	0.015
Zinc-T	<0.0064	<0.0078	<0.0068	0.025			

All concentrations are mg/L. All metal concentrations are for dissolved metals.
Method used to derive representative ambient water quality concentrations described in ERO 2011c.
Concentrations presented with a < symbol had at least one sample with a reported concentration less than the detection limit used in calculating representative values; detection limit used in calculating representative value when reported concentration was below the detection limit.
Predicted concentrations greater than BHES Order limits or applicable nondegradation criteria without additional primary treatment before land application are shown in **bold**.
[1] BHES Order limits apply to only to those parameters for which limits were set in 1992: total dissolved solids, nitrate, chromium, copper, iron, manganese, and zinc.
[2] No increase in ambient concentrations outside of a mixing zone designated by the DEQ applies to degradation determination in nondegradation review for arsenic beryllium, and mercury.
[3] Trigger values apply to degradation determination in nondegradation review for antimony, barium, cadmium, lead, nickel, selenium, and silver.
[4] 15% of lowest standard only applies to degradation determination for concentrations of toxins (antimony, barium, cadmium, copper, lead, nickel, selenium, and silver) outside of a mixing zone designated by the DEQ if the change in water quality exceeds the trigger value.
Source: Appendix G.

MMC's proposal in Alternative 2 to collect and ship sanitary waste off-site for treatment and disposal was not feasible. In Alternatives 3 and 4 during the Evaluation, Construction, Closure and Post-Closure Phases, MMC would use a septic system consisting of septic tanks for primary treatment, followed by discharge to a leach field at the Libby Adit. Expected discharge is 585 gallons per day (Geomatrix 2010a). Using Montana DEQ guidelines for performing a nitrate sensitivity analysis for the septic system (DEQ 2010b), the resultant nitrate concentration calculated at the end of a groundwater mixing zone is 0.75 mg/L. The DEQ guidelines were also used for assessing compliance with nondegradation using a surface water dilution analysis (trigger value calculation) for nitrate and phosphorus. Using the proposed treatment system, the calculated increase in the concentration of nitrate (0.0099 mg/L) and phosphorus (0.0007 mg/L) did not exceed the trigger values of 0.01 mg/L for nitrate and 0.001 mg/L for phosphorus (Geomatrix 2010a). The nondegradation criteria do not apply for nitrate in groundwater or for TIN in surface water for the Montanore Project because the BHES Order set limits of 10 mg/L for nitrate in groundwater and 1 mg/L for TIN in surface water. The assessment results showed that the BHES Order limits would not be exceeded for nitrate in groundwater or TIN in nearby Libby Creek.

During Operations, MMC would use a similar system consisting of septic tanks for primary treatment, followed by discharge to the tailings impoundment for final disposal. Disinfection of effluent from the septic tanks would occur before pumping to the impoundment, and would be accomplished by chlorination, ozonation, or ultraviolet light. Disinfection would reduce the number of microorganisms and eliminate potential hazards due to human exposure to the water in the impoundment. About 6,100 gallons per day or a rate of 5 gpm of sanitary wastewater is estimated to be produced through employee use; a rate of 7,000 gallons per day was used for design purposes (Geomatrix 2010a). The estimate is based on 30 office workers (12 gallons per day) and 230 miners/mill workers (25 gallons per day). Sending treated sanitary wastes to the tailings impoundment would not have a detectable effect on surface water or groundwater quality.

3.13.4.3.3 Stormwater Runoff, Erosion, and Sediment Control

The small amount of water diverted around the Poorman Tailings Impoundment Site from the small watershed above the impoundment would not measurably affect the water quality of Little Cherry or Poorman creeks. The quality of the water is expected to be similar to the receiving water quality. In Alternative 3, no diversion channel for Little Cherry Creek would be constructed, and disturbance associated with such a structure would not occur. The disturbance area surrounding the tailings impoundment would be about 300 acres less than Alternative 2 and the potential for erosion and sedimentation to streams would be less than Alternatives 2 and 4.

When the impoundment was no longer needed to store water from the seepage collection and pumpback well systems during the Closure or Post-Closure Phase, a channel would be excavated through the tailings and Saddle Dam abutment at the Poorman Impoundment to route runoff from the site toward a tributary of Little Cherry Creek. The runoff channel would be routed at no greater than 1 percent slope and along an alignment requiring the shallowest depth of tailings to be excavated down to the channel grade. The side slopes would be designed to a stable slope and covered with coarse rock to prevent erosion. As part of the final closure plan, MMC would complete a hydraulic and hydrologic (H&H) analysis of the proposed runoff channel during final design, and submit it to the lead agencies and the Army Corps of Engineers for approval. The H&H analysis would include a channel stability analysis and a sediment transport assessment. Based on the analysis, modifications to the final channel design would be made and minor modifications to the upper reaches of the tributary of Little Cherry Creek may be needed to minimize effects on channel stability in the tributary of Little Cherry Creek. These measures would minimize erosion and sedimentation of Little Cherry Creek.

Stormwater flow at all facilities would be managed to minimize erosion and sedimentation movement from project facilities and disturbed areas. Ditches and sediment ponds containing process water or mine drainage would be designed for the 100-year/24-hour storm to minimize potential overflow to nearby streams. The Libby Plant Site would be more than 500 feet from Libby Creek, minimizing the potential for non-channelized overland flow to reach Libby Creek (Belt *et al.* 1992). LAD Areas would not be used in Alternative 3, eliminating the LAD Areas as a potential source of erosion. A diversion dam and channel for the Poorman Impoundment Site would not be needed, and disturbance associated with such structures would not occur in Alternative 3. The disturbance area surrounding tailings impoundment would be about 300 acres less than Alternative 2 and the potential for erosion and sedimentation to streams would be less than Alternatives 2 and 4.

In Alternatives 3 and 4, MMC would implement BMPs and road closure mitigation, some which would be completed before the Evaluation Phase and some before the Construction Phase. Other roads would be closed at the end of operations. With BMPs, the KNF's WEPP analysis estimated sediment delivery from roads to streams to be 170 tons, a reduction of 226 tons from existing conditions during the 30-year analysis period (Table 125) (KNF 2013). KNF implements BMPs on roads when they are upgraded for various purposes; the comparison to existing conditions assumes none of the roads used for Alternative 3 would be upgraded in the foreseeable future without the project. A reduction in sediment is anticipated in the following streams: Bear, Big Cherry, Cable, Crazyman, East Fork Rock, Getner, Hoodoo, Libby, Little Cherry, Midas, Poorman, Ramsey, and Standard creeks (KNF 2013).

Sediment and runoff from all disturbed areas would be minimized through the use of BMPs developed in accordance with the Forest Service's *National Best Management Practices for Water Quality Management on National Forest System Lands* (USDA Forest Service 2012a). To reduce sediment delivery to analysis streams, MMC would complete reclamation work at five sites in Libby Creek, Little Cherry Creek, and Poorman Creek, as discussed in the agencies' mitigation plan in Chapter 2 (section 2.5.7.1.2, *Jurisdictional Waters*). After the activities were completed, and the roads became stabilized, sediment delivery to area streams would decrease below existing levels. In the event that a large runoff-producing storm occurred during the initial reclamation period, soil losses along roads and road cuts may be locally moderate to severe. As discussed under Alternative 2, MMC may request and the DEQ may authorize a short-term exemption from surface water quality standards for total suspended sediments and turbidity for construction of the powerline, access roads, the tailings impoundment, and other stream crossings.

To control dust on mine access roads, MMC would use either a chemical stabilization, groundwater, or segregated mine or adit water with nitrate concentrations of 1 mg/L or less and with concentrations of all other parameters below the mine drainage ELG. This mitigation would reduce the potential for adversely affecting water quality.

3.13.4.3.4 Effect of Nitrogen and Sulfur Emissions on Area Lakes

Maximum modeled nitrogen and sulfur emissions from the exhaust adit at the Libby Adit Site during operations in Alternative 3 are predicted to be less than deposition analysis thresholds at Upper Libby Lake, Lower Libby Lake and Rock Lake (see Table 61, p. 300). Modeled rates were highest at Rock Lake, at 0.00459 kilograms/hectare/year, slightly below the deposition analysis threshold of 0.005 kilograms/hectare/year. The agencies' mitigation, such as limiting generator use at the mill after power was available from a transmission line to 16 hours during any rolling 12-month time period and using Tier 4 engines and ultra-low diesel fuel in underground mobile equipment, would substantially reduce emissions compared to Alternative 2. Nitrogen and sulfur emissions from the mine would substantially decrease when underground mining ceased and would end after the adits were plugged.

In Alternatives 3 and 4, MMC would monitor nitrogen and sulfur emissions at the Libby Adit for a minimum of 2 years. Using the monitoring data, MMC would update the nitrogen and sulfur deposition analysis and compare it the updated model results to the current FLM deposition analysis thresholds. If modeled results using the Libby Adit monitoring data were greater than current FLM deposition analysis thresholds, MMC would develop and implement available control technologies to reduce pollutant emissions.

3.13.4.3.5 Risk of Impoundment Failure

The agencies evaluated the risks associated with impoundment construction, operations, and closure using the same failure modes effects analysis used in Alternative 2 (Klohn Crippen Berger 2009). The Poorman impoundment had a similar risk profile as the Little Cherry Creek impoundment. Three failure modes that potentially could affect water quality had risk levels slightly higher than the Little Cherry Creek impoundment. These three failure modes had a moderately low risk level. The increased risk was associated with use of more complex technology, and the closer proximity to Libby Creek and private land (Klohn Crippen Berger 2009). The likelihood of failure is discussed in section 3.14.3 of the *Geotechnical* section.

3.13.4.3.6 Climate Change

The effects of climate change in combination with Alternative 3 would be the same as in combination with Alternative 2.

3.13.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Alternative 4 would be similar to Alternative 3, including the same mitigations to protect surface water, but would have modifications to MMC's proposed Little Cherry Creek Tailings Impoundment as part of the alternative. The total disturbance area for Alternative 4 would be 1,924 acres. The following sections discuss only those effects that would be different than Alternatives 2 or 3. The effects of discharges and nitrogen and sulfur emissions from the exhaust adit at the Libby Adit Site would be the same as Alternative 3.

3.13.4.4.1 Effects of Mine Inflows and Discharges

The effects on surface water and groundwater quality would be the same as Alternative 3, except for effects at the tailings impoundment site. Groundwater quality after mixing with seepage beneath the Little Cherry Creek Impoundment Site would be the same as Alternative 2 (Table 126). As discussed in Alternative 2, groundwater metal concentrations beneath the impoundment area may be less than those predicted by the mass balance calculations. The discussion in Alternative 2 of mixing zones in surface water (at LB-300 in Alternative 4) and groundwater at the tailings impoundment site would apply to Alternative 4. During the MPDES permitting process, the DEQ would make the same determinations regarding a mixing zone for discharges in Alternative 4 that were discussed in Alternative 2.

3.13.4.4.2 Stormwater Runoff, Erosion, and Sediment Control

Stormwater flow at all facilities would be managed in the same manner as Alternative 3. The effects from the Libby Plant Site and the elimination of LAD Areas as a potential source of erosion would be the same as Alternative 3. Ditches and sediment ponds containing process water or mine drainage would be designed for the 100-year/24-hour storm to minimize potential overflow to nearby streams. The use and inspection of BMPs would be the same as Alternatives 2 and 3.

At the tailings impoundment, the Diversion Channel would consist of two main sections: an upper engineered channel and a constructed lower channel to Libby Creek using Drainage 10 as proposed in Alternative 2. The engineered channel would be the same as the engineered channel in Alternative 2 and would be designed for the 6-hour probable maximum flood. To reduce the contribution of sediment to the diverted Little Cherry Creek, water would flow into a constructed channel that would be designed to be geomorphically stable and adequate to handle the 2-year flow event estimated for the increased watershed size. A floodplain would be constructed along the channel to allow passage of the 100-year flow.

MMC also would evaluate potential locations for ponds to capture and retain sediment from the two channels and for creating wetlands in the floodplain of Libby Creek. The majority of sediment generated would occur during the initial channel flush after construction and subsequent high flow and runoff events. In the event of heavy precipitation during construction of the channel, substantial erosion and short-term increases in sedimentation to the lower channel and Libby Creek would occur. Natural and biodegradable materials and vegetation would be used along stream banks and on the floodplain to minimize erosion, stabilize the stream channel and floodplain, and minimize sedimentation to the lower channel and Libby Creek. MMC would construct bioengineered and structural features in the two channels to reduce flow velocities, and minimize erosion and sedimentation, where access was possible to complete such work. Long-term monitoring and maintenance would be required until the agencies determine that the channel was stabilized. With these mitigation measures, the naturally designed constructed channel may be subject to erosion and sedimentation during construction and until vegetation stabilized the stream banks and floodplain.

Following reclamation of the impoundment, the constructed channel would undergo an additional period of channel adjustment when runoff from the impoundment surface would be directed to the Diversion Channel. No runoff would be diverted to Bear Creek as in Alternative 2. The increase in flow to the constructed channel would be about 50 percent higher at closure than during operations. The increased flow would likely cause short-term increases in sedimentation in the lower channel and possibly in Libby Creek. In the long term, runoff from the impoundment would decrease and eventually cease. Sedimentation in the lower channel and Libby Creek would not be expected to occur except during storm events larger than the channel was designed to handle.

The KNF's WEPP analysis found that road closure mitigation and implementation of BMPs would result in a total sediment delivery to streams from roads of 175 tons, a reduction of 228 tons compared to existing conditions during the 30-year analysis period (Table 125) (KNF 2013). The BMPs and monitoring discussed under Alternative 2 would be implemented to minimize sediment reaching streams. A reduction in sediment is anticipated in the following streams: Bear, Big Cherry, Cable, Crazyman, East Fork Rock, Getner, Hoodoo, Libby, Little Cherry, Midas, Poorman, Ramsey, and Standard creeks (KNF 2013).

3.13.4.4.3 Risk of Impoundment Failure

The agencies did not specifically evaluate the risks associated with the agencies' modifications to the Little Cherry Creek impoundment. The Little Cherry Creek impoundment in Alternative 4 would have a similar risk profile as Alternative 2.

3.13.4.5 Uncertainties Associated with the Water Quality Assessment

Changes in surface water and groundwater quality were projected using an analytical technique known as a chemical mass balance analysis. The mass balance analysis estimates the changes in concentrations of metals and other constituents in a receiving stream when discharges from the proposed operation are added. Projected changes in groundwater concentrations are calculated in a similar manner. The projections assume complete mixing of the discharged wastewater and ambient receiving waters. Variables used in the mass balance analysis include flow rate and ambient water quality in the receiving stream, and the rate and water quality of the proposed discharges.

The mass balance analysis uses the estimated wastewater quality shown in Appendix K and the discharged quantities provided in the water balances for each alternative to predict the resulting water quality after mixing with ambient water quality at low flows. At the LAD Areas, average precipitation and evapotranspiration rates for the 6-month growing season were used.

Projections of surface water quality involve a number of uncertainties. These include the ambient and discharge water qualities, ambient water quantities, the effectiveness of treatment of the various water quality parameters by the Water Treatment Plant or land application, discharge water quantities, the effectiveness of mixing in the stream, the exact location where surface water would be affected, and the environmental effect from increased metal concentrations on aquatic life. Because of the complexity of the water quality assessment, each of these uncertainties is discussed briefly in the following sections.

3.13.4.5.1 Ambient Water and Wastewater Quality

Mean or median water quality concentrations of ambient water and wastewater frequently could not be easily estimated because reported water quality concentrations for many parameters, particularly metals, were below the analytical detection limits. The detection limit is the lowest concentration of a parameter detectable by a laboratory using a particular analytical procedure. Parameters with concentrations reported with a "less than" symbol (<) are those parameters with concentrations below the detection limit. For concentrations reported with a less than symbol, the value shown is the "detection limit" reported by the analytical laboratory. If a concentration of a parameter is below the detection limit, the actual concentration is not absolutely known.

In developing estimates of ambient water and wastewater quality, the agencies used the detection limit in determining a representative concentration when the reported concentration was below the detection limit. For all assessment locations, representative concentrations of all samples collected at a particular location were used to represent concentrations during low flow conditions. The method for deriving representative concentrations is described in the *Final Baseline Surface Water Quality Technical Report* (ERO Resources Corp. 2011c). Representative concentrations may be higher or lower than actual concentrations during low flow periods. The projected final concentrations after mixing would be greater if the ambient low flow concentration was higher than the representative concentration or lower if the ambient low flow concentration was lower. A comparison of chemical concentration data with corresponding streamflow measurements was generally inconclusive due to a lack of water quality data collection at high flows.

3.13.4.5.2 Geochemical Characterization

Geochemical sampling was limited to ore and waste rock available from archived rock core that was drilled before the withdrawal of the CMW from mineral entry, and to waste rock obtained from exposures within the Libby Adit. Additional geochemical characterization is needed to expand and refine the available data and requires additional sample collection during the Evaluation and Construction Phases of the project. Early (pre-1992) efforts to characterize the geochemistry of the Rock Creek-Montanore and Troy deposits were limited in scope based on the consistent mineralogy observed in the deposits, and vary in the extent to which they meet current expectations of sampling intensity. Available datasets for each of the similar Revett-style deposits focus on geochemical characterization of particular materials. For example, considerably more waste rock data are available for the Prichard and Burke formations at Montanore than for Rock Creek or Troy, but a greater number of ore samples have been characterized at a more comprehensive level for Rock Creek. Many more water quality monitoring data have been collected over 30 years of operation under facility specific conditions (*e.g.,* underground workings or tailings impoundment) at Troy than at Rock Creek or Montanore.

The elements of uncertainty related to the extent of sampling, such as collection of waste rock from unexposed portions of the Revett, Prichard and Burke formations or analysis of bulk tailings samples for Montanore-specific ore zones, are addressed in the sampling and analysis plans described in Appendix C and by Geomatrix (2007a). The elements of uncertainty related to the use of monitoring data from the geochemical analog at the Troy Mine would also be addressed through Evaluation and Operations Phase monitoring as defined in Appendix C.

Environmental geochemistry data were collected for Montanore, as well as Rock Creek and Troy, for more than 20 years. Changes in analytical methods and quantitation limits have resulted in analysis of different analytes and reporting of multiple detection limits, particularly for trace metals. The absence of some regulated parameters in particular analyses, or the reporting of below detection limit values for some elements at levels above current standards, both introduce uncertainty into predictions of metal mobility for proposed facilities. The need for more comprehensive analyses of metals, at appropriate detection limits, when representative samples of ore, waste, and tailings are accessible in the evaluation adit is addressed in the agencies' Geochemical Sampling and Analysis Plan provided in Appendix C.

Laboratory and field data offer different strengths and limitations that complement one another in predictions of future water quality. Laboratory analyses test the potential for sulfide oxidation and metal release under controlled, pre-defined, short term experimental conditions (*e.g.,* surface area, dilution, oxygen exposure, acidity, etc.), while *in situ* monitoring provides a measurement of these geochemical processes under longer term, field-scale conditions. Laboratory tests can evaluate specific subsamples representative of the range of natural variation, while field-scale studies integrate that variation into a single measurement. It is typically easier to test discrete representative samples under laboratory conditions than to obtain equally representative *in situ* data, particularly for a facility that has not yet been built. The ability to compare results from multiple samples tested using accepted laboratory methods, within and across several Revett-style deposits, with long-term monitoring data from the Libby Adit and Troy Mine reduces uncertainty in predictions made for the Montanore Project. Collection of additional data as specified in the geochemistry sampling and analysis plan provided in Appendix C would reduce the identified uncertainty and allow MMC to appropriately modify waste rock and water management plans before beginning mining operations. Operational monitoring of mined materials and water quality, as recommended by Geomatrix (2007a), and refinement of baseline predictions would allow further reduction of uncertainty before closure.

3.13.4.5.3 Ambient Water Quantity

Surface water low-flow conditions are conservative flows for assessing impacts from pollutant discharges. For the mass balance analysis, estimated $7Q_{10}$ flow were used for assessing potential impacts on surface water quality, or, for LB-300, the modeled baseflow was used (see section 3.13.2.2.2, *Impact Analysis*). Use of a $7Q_{10}$ flow is consistent with the DEQ's standard surface water mixing zone rules (ARM 17.30.516). Measured low flows during the baseline monitoring period were lower at some assessment locations than the estimated $7Q_{10}$ flow. Flows lower than the $7Q_{10}$ flow would result in less dilution and higher instream concentrations than projected, if other assumptions in the mass balance analysis remained constant. Flows higher than the baseflow used in the LB-300 analysis would result in more dilution and lower instream concentrations than projected, if other assumptions in the mass balance analysis remained constant.

A groundwater flux was estimated for assessing impacts on groundwater beneath the two tailings impoundment sites and LAD Areas. MMC's and the agencies' estimates of groundwater flux are based on available data from the two tailings impoundment sites and LAD Areas. To derive groundwater flux, estimates of groundwater gradient and hydraulic conductivity are required. If actual conductivities or gradients were higher than estimated, more water would be available for mixing, and lower groundwater concentrations than those projected would occur. Groundwater flux less than the estimated flux would result in less water available for mixing and higher groundwater concentrations than projected, if other assumptions in the mass balance analysis remained constant.

3.13.4.5.4 Wastewater Quantity

Projected wastewater quantity is based on the estimated water balance for each alternative. Water balances are point estimates of water production and use, developed using standard methods and reasonable assumptions. Actual flow rates for a number of water sources described by the water balance, such as precipitation, evaporation, and dust suppression, would vary seasonally and annually from the rates shown in the estimated water balances. Actual mine and adit inflows would vary as the mine would be developed, partly in response to short-term higher flows from fractures and faults intersected by the mine void, and partly in response to increasing the volume of the mine void as mining progresses. Grouting would reduce mine and adit inflows. The groundwater model provides estimates of mine and adit inflow as mining progresses, but does not consider short-term higher inflow from dewatering fractures and faults.

The agencies used mine and adit inflows predicted by the 3D model by phase to assess impacts on surface water and groundwater quality. Mine and adit inflows actually encountered during all mine phases may be higher or lower than those predicted by the 3D model. Although the 3D model predicted a maximum short-term peak of 800 gpm, the short-term peak of 800 gpm assumed instantaneous development of two new adits and therefore over-estimated peak inflows. The amount of wastewater discharged during each mine phase to the Water Treatment Plant (all alternatives) or to the LAD Areas (Alternative 2 only) would depend on mine and adit inflow rates. Discharge rates at the Libby Adit Site outfalls are limited in the existing MPDES permit by an annual average load limit. MMC would expand the capacity of the Water Treatment Plant to accommodate discharges during the estimated wettest year in a 20-year period. During the MPDES permitting process, the DEQ would determine if load limits in the permit would be changed. The DEQ may also issue an MPDES permit that allowed for seasonal variations in the allowed maximum discharge rate, which would be greater during months when streamflow was higher, and lower during low flows rather than the constant discharge rates used for each mine phase in the EIS analysis. The agencies' estimate of the discharge rate to the LAD Areas for Alternative 2 is presented in Appendix G and discussed in section 3.10.4.2.1, *LAD Areas* of the *Groundwater Hydrology* section. Because of uncertainties in the operational water balance and the discharge rates, the agencies would require monitoring of flows and discharges during all mine phases (Appendix C).

3.13.4.5.5 Water Quality Assessment Locations

In all alternatives, water from the Water Treatment Plant would discharge to a percolation pond adjacent to Libby Creek or, when the percolation pond reached capacity, to Libby Creek immediately upstream of LB-300. In Alternatives 3 and 4, discharges may be needed in Ramsey Creek to protect senior water users or to Libby Creek at a location lower than LB-300 if DEQ determines flow changes are significant. Any Water Treatment Plant discharge location would be monitored as required by the MPDES permit. For Alternative 2, some uncertainty is associated with how and where streams would be affected by discharges from the LAD Areas. In projecting impacts on surface water quality, the agencies chose monitoring stations on Ramsey Creek, Poorman Creek, and Libby Creek, some of which are long-term water quality monitoring sites. For example, the agencies estimated the percentage of the wastewater from LAD Areas 1 and 2 for Alternative 2 that would flow to Ramsey Creek, Poorman Creek, or Libby Creek based on site topography; the actual rate of discharge to each stream may be different. In addition, the locations in each stream at which water from the LAD Areas would discharge may be above or below the monitoring locations used for the impact analysis. A station on Libby Creek (LB-1000) was used to assess the effects of all discharges in Alternative 2.

3.13.4.5.6 Land Application Treatment

Land application of mine wastewater is proposed only for Alternative 2. Land application treatment is site- and effluent-specific. The amount of precipitation that occurs on a land treatment site, the quality of the precipitation, and the rate of evapotranspiration from the land treatment site, are variable and uncertain. Many factors affect treatment effectiveness. The treatment rates for total dissolved solids, nitrogen, and metals are uncertain (see LAD Area discussion under section 3.13.4.2.1, *Evaluation and Construction Phases*). It is not possible to estimate actual removal rates for total dissolved solids, nutrients, and metals until mine wastewater application to the LAD Areas occurred and monitoring data were collected. For the analysis of the effects of land application of wastewater, it was assumed that there would be no operational issues at the LAD Areas, such as uneven application of wastewater or runoff from the site directly to streams before treatment. It was also assumed that the treatment rates would not change over time, which may be realistic if the LAD Areas were properly monitored, inspected, and maintained.

For the water quality impact analysis, it was assumed that the percolation of treated groundwater from the LAD Areas would be essentially a direct discharge into the receiving stream. Depending on the effective porosity of the aquifer under the LAD Areas (which is unknown, but estimated) and the actual flow path, the water treated at the LAD Areas may take from less than a year up to 10 years to reach receiving streams.

3.13.4.5.7 Environmental Effects on Aquatic Life

The concentration at which metals and nutrients affect aquatic life in the analysis area is uncertain. Montana surface water quality standards shown in Table 118 are based on a hardness of 25 mg/L as calcium carbonate ($CaCO_3$); actual hardness in area streams ranges between about 5 and 25 mg/L. Environmental effects on aquatic life from those metals that are hardness-related (cadmium, chromium, copper, lead, nickel, silver, and zinc) may occur at concentrations less than those shown in Table 118. The BHES Order established a limit of 1 mg/L for total inorganic nitrogen, and the DEQ nutrient regulations have a standard of 0.275 mg/L for total nitrogen and 0.025 mg/L for total phosphorus. A general variance to the total nitrogen and total phosphorus concentrations, if granted by DEQ to MMC, would allow a variance at the end-of-pipe at the Water Treatment Plant of 10 mg/L for total nitrogen and 1 mg/L for total phosphorus. The BHES Order limit of 1 mg/L for TIN may be the applicable limit for total nitrogen because nitrate would be the dominant nitrogen form in the Water Treatment Plant effluent. The uncertainty of effects to fish and other aquatic life of nitrogen and phosphorus concentrations being within these limits in Libby Creek downstream of the Water Treatment Plant discharge point is discussed in section 3.6, *Aquatic Life and Fisheries*.

3.13.4.6 Effectiveness of Agencies' Proposed Monitoring and Mitigation Plans

3.13.4.6.1 Monitoring

Geochemical Monitoring

Additional sampling would be conducted during the Evaluation, Construction, and Operations Phases, when a more representative section of waste rock would be available for sampling. Characterization of metal release potential for tailings and waste rock is limited and would be expanded in Alternatives 3 and 4. Descriptions of mineralogy in rocks exposed by the evaluation adit ore zone (for the Revett Formation) and development adits (for the Burke and Prichard formations) would be used to identify subpopulations with sulfide altered waste zone overprints. Their relative importance, in terms of tonnage to be mined, would guide sampling density. If the Wallace Formation was intercepted, samples of the lithology would be collected and characterized. The information would be used to redefine geochemical units for characterization and evaluate potential selective handling and encapsulation requirements.

Waste rock would be stockpiled and runoff from the pile would be contained and treated, if necessary. Waste rock would be used at the impoundment site for dam construction, using selective handling criteria that would be defined during the Evaluation Phase (see section C.9.7, *Data Analysis*). It is not clear which fraction of the Revett Formation waste rock would be brought to the surface. Once more detailed information about the Revett and Prichard formations waste rock was available during the Evaluation Phase, along with updated predictions of metal concentrations for tailings, these sources would be incorporated into updated mass balance calculations found in Appendix G.

Surface Water and Groundwater Monitoring

The agencies' plan (Appendix C) includes monitoring of all surface water bodies and groundwater potentially affected by the project, including collection of additional water quality, flow and lake level data before the Evaluation and Construction Phases. The plan also includes action levels based on monitoring data that would trigger corrective measures to be implemented by MMC. The agencies anticipate that the monitoring plan would successfully identify, measure, and separate water quality effects due to mining from natural variability. To accomplish this, MMC would be required to collect water quality samples from benchmark reference sites located near the analysis area, but outside of the area that might be affected by the project (Appendix C). The benchmark sites would be subject to similar ranges in parameters that cause natural variability of data within the analysis area, such as precipitation and temperature. These benchmark sites would include Wanless Lake, a lake similar to Rock Lake, Swamp Creek, a stream west of the divide similar to upper East Fork Rock Creek and East Fork Bull River, and Bear Creek, a stream east of the divide similar to upper Libby Creek. The monitoring plan would be evaluated during each mine phase and modified if needed. The action levels and associated corrective measures, as well as adaptive management, would be effective in minimizing the potential for adverse changes in surface water or groundwater quality.

3.13.4.6.2 Mitigation for Changes in Sediment Delivery to Streams

1. The disturbance area of Alternatives 3 and 4 would be less than Alternative 2, which would effectively minimize sediment delivery in all analysis area streams.

2. In Alternatives 3 and 4, runoff from the reclaimed tailings impoundment would be directed toward Little Cherry Creek instead of Bear Creek proposed in Alternative 2. As part of the final closure plan, MMC would complete a H&H analysis of the proposed runoff channel during final design that would include a channel stability analysis and a sediment transport assessment. The runoff channel would be effective in minimizing adverse effects of increased streamflow on Little Cherry Creek.

3. In Alternatives 3 and 4, MMC would develop and implement a Road Management Plan addressing all roads used, closed, and stabilized in the alternative. MMC would complete reclamation work at five sites in Libby Creek, Little Cherry Creek, and Poorman Creek to reduce sediment delivery to analysis streams. Twenty-five roads would be closed, some before the Evaluation Phase, some before the Construction Phase, and some during the Closure Phase to mitigate for project access effects on grizzly bears. After roads were stabilized and revegetated, sediment delivery to area streams would cease and overall sediment delivery to analysis area streams would be about 90 tons less to analysis area streams after all of the roads were closed. Road closures would have direct and long-lasting beneficial effects on sediment delivery in all analysis area streams. The agencies expect BMPs implemented to minimize sediment delivery from affected forest roads to be between 88 and 99 percent effective (KNF 2013). MMC would implement and maintain all appropriate BMPs for roads during their use by the project. Appropriate BMPs would be those that: 1) disconnect road surfaces and drainage ditches from streams; 2) shorten road surface lengths draining to surface waters; 3) seed and revegetate disturbed soils; and 4) harden road surfaces. BMPs that accomplish these would be the most effective way to minimize sediment delivery from affected forest roads.

4. In the agencies' preferred alternative (Alternative 3), the tailings impoundment would be at the Poorman Impoundment Site, which would not require the diversion of Little Cherry Creek. The elimination of potential erosion and sediment delivery to the diverted Little Cherry Creek and Libby Creek associated with the diversion would reduce water quality effects on the diverted Little Cherry Creek. In Alternative 4, the tailings impoundment

would be in the Little Cherry Creek channel. The diversion channel would be designed to minimize erosion and sedimentation in the diverted Little Cherry Creek and Libby Creek

3.13.4.6.3 Mitigation for Other Water Quality Changes

5. The LAD Areas would not be used in Alternatives 3 and 4 and all excess water would be treated at the Water Treatment Plant before discharge. Effluent discharged from the Water Treatment Plant to Libby Adit Site outfalls would be required to meet the MPDES permitted effluent limits. The Water Treatment Plant would be designed to treat up to the rate estimated for the wettest year in a 20-year period. The use of a high-capacity Water Treatment Plant would be effective in ensuring effluent limits were met and beneficial uses protected. Effluent limits would need to be very low to avoid significant degradation during low flow conditions; therefore, DEQ might issue an MPDES permit that allowed for seasonal variations in the allowed maximum discharge rate, which would be greater during months when streamflow is higher, and lower during low flows. Alternatives 3 and 4 would have only one point of discharge, which could be much more effectively monitored and controlled.

6. Pumpback wells would be used to capture all seepage from the tailings impoundment that reached groundwater, which would minimize effects to groundwater quality and prevent any seepage from reaching nearby streams and affecting surface water quality. Whether the pumpback wells would effectively capture all of the seepage would be determined by installing numerous monitoring wells downgradient of the pumpback wells (Appendix C). MMC would monitor downgradient wells to detect any groundwater quality changes. If water quality changed at compliance wells due to inadequate capture by the pumpback wells, MMC would be required to increase pumping rates or install additional pumpback wells. Maintaining capture of tailings seepage would be effective in minimizing effects on surface water quality.

7. Runoff and seepage from waste rock stockpiles would be collected and treated at the Water Treatment Plant during the Construction Phase, or used in milling operations during the Operations Phase. Establishment of selective handling criteria and waste rock management in Alternatives 3 and 4 would effectively eliminate waste rock in impoundment dam construction as a potential source for affecting the quality of streams and groundwater within the analysis area.

8. Based on preliminary design, the Libby Plant Site would not be built with waste rock. If waste rock was not used to build the plant site, waste rock would be eliminated as a potential source of metals and nutrients in infiltration and surface water runoff.

9. As needed to minimize water quality effects on the west side streams, springs and lakes, buffer zones would be maintained near Rock Lake and the Rock Lake Fault. The buffer zone thickness would be reassessed through the use of an updated hydrologic model.

10. After the mine area groundwater model was updated at the end of the Evaluation Phase, MMC would submit an updated mine plan to the agencies for approval. The mine plan would identify two barrier pillars 20 feet wide across the width of the ore body that would be left in place (except for openings needed for access) during the first 5 years of mining until additional refinement of the hydrologic model was completed and the need for barrier pillars was evaluated. By the fifth year of operations, MMC would assess the

need for barrier pillars and/or bulkheads to minimize post-mining changes in East Fork Rock Creek and East Fork Bull River streamflow and water quality. If needed, MMC would submit a revised mine plan to the agencies for approval. Grouting would also be implemented in the mine during construction and operations. These mitigations would be effective in reducing wastewater discharges and the potential risk of post-mining water quality effects on west side streams and Rock Lake.

11. Tailings and reclaimed water pipelines would be buried, which, along with a leak detection system, would be effective in reducing the risk of any tailings or reclaimed water reaching surface water resources.

12. Treating sanitary waste on-site (as described in section 2.5.4.4) and pumping to the tailings impoundment during operations rather than storing and shipping off-site for disposal would effectively reduce the risk of untreated sanitary wastewater reaching surface water or groundwater.

13. MMC would comply with Forest Service policies when disposing of demolition debris during closure. It is Forest Service policy to discourage the disposal of solid waste on National Forest System lands unless such use is the highest and best use of the land. No solid wastes other than waste rock would be buried underground in mined-out areas. Limiting solid waste disposal on National Forest System lands would be effective in minimizing effects on groundwater quality from waste disposal.

14. To further reduce the potential for metals and sediment to reach analysis area streams, ditches and sediment ponds that would contain process water or mine drainage would be designed for a 100-year/24-hour storm (rather than the 10-year/24-hour storm proposed in Alternative 2). This mitigation would be more likely to capture all stormwater containing process water or mine drainage during the life of the project and would be effective in reducing water quality effects on east side streams.

15. In Alternatives 3 and 4, to control dust on mine access roads, MMC would use either a chemical stabilization, groundwater, or segregated mine or adit water with nitrate concentrations of 1 mg/L or less and with concentrations of all other parameters below the mine drainage ELG. This mitigation would be effective in eliminating effects on water quality from dust suppression watering.

16. After the electric transmission line (either the 34.5-kV underground line or the 230-kV overhead line) was operational at the mine site, the operation of the diesel generator at the mill would not exceed 16 hours during any rolling 12-month time period (DEQ 2011a). Tier 4 engines and ultra-low sulfur diesel fuel also would be used in underground mobile equipment. These measures would be effective in reducing nitrogen and sulfur deposition into wilderness lakes.

3.13.4.7 Alternative A – No Transmission Line

In Alternative A, the transmission line, substation, and loop line for the Montanore Project would not be built. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Possible impacts on streams due to construction, operations, and maintenance of a new transmission line would not occur.

3.13.4.8 Alternative B – MMC Proposed Transmission Line (North Miller Creek Alternative)

The Ramsey Plant Site's electrical service would be provided via a new, overhead transmission line. MMC's proposed alignment would be in the Fisher River, Miller Creek, Midas Creek, Libby Creek, and Ramsey Creek watersheds. This alternative would create the greatest amount of disturbance close to streams because it would have the highest new road mileage and disturbed acreage in areas with severe erosion risk, high sediment delivery to nearby streams, and greatest slope failure potential (see Table 166, p. 855). Possible sediment sources would include new road construction, existing road upgrades, timber and vegetation clearing, soil salvage, and structure installation. The highest risk of increased sedimentation would occur during the Construction Phase of the transmission line, when vegetation was removed from the transmission line corridor, substation site, and access roads.

Occasional short-term increases in the amount of sediment in analysis area streams would be likely within all watersheds. Alternative B would have the greatest effect within the watersheds of impaired streams (Table 130) and Class 1 streams (Table 131). Alternative B would parallel about 4.7 miles of line in the Fisher River, where soils with severe erosion risk and high sediment delivery are found. Two structures and a new road would be required immediately adjacent to the river near the Fisher River crossing. Clearing for the transmission line would disturb about 82 acres in the watershed, and new or upgraded roads would disturb 2 acres (Table 130). As discussed under Alternative 2, MMC may request and the DEQ may authorize a short-term exemption from surface water quality standards for total suspended sediments and turbidity for construction of the powerline, access roads, and other stream crossings.

Construction of the Sedlak Park Substation and loop line would not affect water quality. The BPA would obtain a general permit from the DEQ for any stormwater discharges. The BPA would prepare and implement a SWPPP during substation and loop line construction to minimize water erosion. The substation site would have a stormwater containment system.

Alternative B line clearing also would disturb 15 acres and 2 acres by new or upgraded roads in the Libby Creek drainage. Tree clearing across Libby Creek would be 150 feet wide. The soils at the Libby Creek crossing have severe erosion risk and high sediment delivery. Libby Creek starting at 1 mile above Howard Creek is listed for alteration in streamside vegetative cover, which could result in additional sediment delivery to the creek, and Libby Creek below the US 2 bridge is listed as impaired for sediment and siltation. To address the sediment TMDL on Libby Creek, MMC would implement BMPs included in the MPDES permit to meet the sediment wasteload allocation of 24 tons/year developed by DEQ for the project.

Table 130. Transmission Line Disturbances in the Watersheds of Impaired Streams.

Criteria	Alternative B North Miller Creek (ac.)	Alternative C-R Modified North Miller Creek (ac.)	Alternative D-R Miller Creek (ac.)	Alternative E-R West Fisher Creek (ac.)
Fisher River Watershed				
Clearing area†	82	21	21	21
New roads + closed roads with high upgrade requirements	2	<1	<1	<1
Libby Creek Watershed				
Clearing area†	15	13	13	13
New roads + closed roads with high upgrade requirements	2	<1	<1	<1

†Acreage is based on a 150-foot clearing width for monopoles (Alternative B) and 200-foot width for H-frame structures (other alternatives except for a short segment of the West Fisher Creek Alternative E-R that has monopoles). Actual acreage cleared would be less than listed and would depend on tree height, slope, and line clearance above the ground.

[†]Existing sediment delivery to streams is for roads that would be used for transmission line access in Alternatives B, C-R, D-R, or E-R.
Source: KNF 2013.

The KNF's WEPP analysis found that roads proposed for use by Alternative B would deliver, with BMPs, an estimated 97 tons of sediment to streams during the 30-year analysis period, a reduction of 17 tons compared to existing conditions for the same roads without BMPs (Table 132). Mitigation to stabilize existing and new roads would include BMPs, revegetation, and access restrictions. After the 2-year closure period, sediment delivery to streams would return to pre-transmission line conditions. A reduction in sediment is anticipated in the following streams: Fisher River, Howard, Libby, Midas, and Miller creeks (KNF 2013).

Implementation of a SWPPP and use of BMPs, Environmental Specifications, and other design criteria would minimize sediment and dust reaching area streams during construction and decommissioning under most conditions, including large runoff-producing weather events. After construction was completed, disturbed areas would be stabilized and revegetated. Erosion and sediment delivery would decrease after vegetation cover was re-established. The DEQ would require on-site inspections of perennial stream crossings to determine the method that would result in minimizing impacts on stream banks and water quality considering the nature and cost of the available crossing methods.

3.13.4.9 Transmission Line Alternatives C-R, D-R, and E-R

The installation of culverts, bridges, or other structures at perennial stream crossings would be specified by the agencies following on-site inspections with the DEQ, Forest Service, FWP, landowners, and local conservation districts. Installation of culverts or other structures in a water of the United States would be in accordance with the U.S. Army Corps of Engineers 404 and DEQ 318 permit conditions. As discussed under Alternative 2, MMC may request and the DEQ may authorize a short-term exemption from surface water quality standards for total suspended sediments and turbidity for construction of the powerline, access roads, and other stream crossings.

3.13.4.9.1 Alternative C-R

The agencies developed two primary alignment modifications to MMC's proposed North Miller Creek alignment in Alternative B. One modification would be routing the line on an east-facing ridge immediately north of the Sedlak Park Substation instead of following the Fisher River. This modification would reduce potential erosion and sedimentation by crossing less area with soils that are highly erosive soils and those with potential for high sediment delivery and slope failure (see Table 166, p. 855) and locating the line farther from streams and wetlands. The other alignment modification would use an alignment up and over a ridge between West Fisher Creek and Miller Creek, reducing clearing in the West Fisher Creek watershed. Other modifications to the alignment are relatively small shifts along an unnamed tributary to Miller Creek that would locate the line farther from these streams and reduce the likelihood of sediment entering the streams. H-frame structures, which generally allow for longer spans and fewer structures and access roads, would be used on this alternative. In some locations, a helicopter would be used to place the structures. These two modifications would reduce potential impacts on water quality by reducing clearing and disturbance associated with new access roads. For analysis purposes, Alternative C-R would end at the Libby Plant Site proposed in Alternatives 3 and 4. Effects would be slightly greater than discussed below if this alternative were selected with Alternative 2 because the plant site would be in the Ramsey Creek watershed.

New road mileage and disturbed acreage would be less in Alternative C-R than Alternative B (see Table 39, p. 222 in Chapter 2; and Table 166, p. 855). Occasional sediment increases would likely still occur within the streams, but the frequency and magnitude of these increases would be less than in Alternative B. The KNF's WEPP analysis found that roads proposed for use by Alternative C-R, with BMPs, would deliver an estimated 150 tons of sediment to streams during the 30-year analysis period, a reduction of 38 tons from existing conditions for the same roads without BMPs (Table 132). Mitigation to stabilize existing and new roads would include BMPs, revegetation, and access restrictions. A reduction in sediment is anticipated in the following streams: Fisher River, Hunter, Libby, Midas, and Miller creeks (KNF 2013).

Alternative C-R would have fewer disturbances in the watersheds of impaired streams than Alternative B (Table 130). Clearing for the transmission line would disturb 21 acres in the Fisher River watershed and 13 acres in the Libby Creek watershed. Tree clearing across Libby Creek would be about 200 feet wide. New or upgraded roads would disturb less than an acre in both watersheds.

3.13.4.9.2 Alternative D-R

Like the Modified North Miller Creek Alternative, this alternative modifies MMC's proposed North Miller Creek Alignment by routing the line on an east-facing ridge immediately north of the Sedlak Park Substation. The crossing of the Fisher River and West Fisher Creek also would be the same as Alternative C-R. Compared to the other alternatives, this alignment would cross less area with soils that are highly erosive soils and those with potential for high sediment delivery and slope failure, reducing the potential for increased sediments in nearby streams (Table 166, p. 855). H-frame structures, which generally allow for longer spans and fewer structures and access roads, also would be used on this alternative, reducing clearing associated with new access roads and potential erosion. For analysis purposes, Alternative D-R would end at the Libby Plant Site proposed in Alternatives 3 and 4. Effects would be slightly greater than discussed below if this alternative were selected with Alternative 2 because the plant site would be in the Ramsey Creek watershed.

New road mileage and disturbed acreage would be less in Alternative D-R than Alternative B (Table 166, p. 855). Occasional sediment increases would likely still occur within the streams, but the frequency and magnitude of these increases would be less than in Alternative B. The KNF's WEPP analysis found that roads proposed for use by Alternative D-R, with BMPs, would deliver an estimated 104 tons of sediment to streams during the 30-year analysis period, a reduction of 30 tons compared to existing conditions for the same roads without BMPs (Table 132). Mitigation to stabilize existing and new roads would include BMPs, revegetation, and access restrictions. A reduction in sediment is anticipated in the following streams: Fisher River, Howard, Hunter, and Miller creeks (KNF 2013).

Effects of Alternative D-R on Class I watersheds and watersheds of impaired streams would be the same as Alternative C-R (Table 130; Table 131). The agencies' mitigation of road closures would reduce the contribution of additional sediment to below existing levels in the Libby Creek watershed. Other effects of Alternative D-R would be the same as Alternative B.

3.13.4.9.3 Alternative E-R

Like the Modified North Miller Creek Alternative, this alternative modifies the North Miller Creek Alternative by routing the line on an east-facing ridge immediately north of the Sedlak Park Substation. The crossing of the Fisher River and West Fisher Creek also would be the same as Alternative C-R. Effects of Alternative E-R on Class I watersheds and watersheds of impaired streams would be the same as Alternative D-R (Table 130; Table 131).

H-frame structures, which generally allow for longer spans and fewer structures and access roads, would be used on this alternative in most locations. In some locations, a helicopter would be used to place the structures. These two modifications would reduce potential impacts on water quality by reducing clearing associated with new access roads. For analysis purposes, Alternative E-R would end at the Libby Plant Site proposed in Alternatives C-R and D-R. Effects would be slightly greater than discussed below if this alternative were selected with Alternative B.

New road mileage and disturbed acreage would be less in Alternative E-R than Alternative B (Table 166, p. 855). Occasional sediment increases would likely still occur within the streams, but the frequency and magnitude of these increases would be less than in Alternative B. The KNF's WEPP analysis found that roads proposed for use by Alternative E-R would deliver an estimated 174 tons of sediment to streams during 30-year analysis period, a reduction of 45 tons compared to existing conditions for the same roads without BMPs (Table 132). Mitigation to stabilize existing and new roads would include BMPs, revegetation, and access restrictions. A reduction in sediment is anticipated in the following streams: Fisher River, Howard, Hunter, Miller, Standard and West Fisher creeks (KNF 2013).

3.13.4.10 Cumulative Effects

Past and current actions, particularly timber harvest, road construction, and mining, have altered surface water quality in the area by increasing sedimentation, destabilizing stream channels and removing streamside vegetation. The DEQ's listing of impaired streams indicates Libby Creek between Howard Creek and the US 2 bridge is impaired due to alteration in stream-side or littoral vegetative covers, and physical substrate habitat alterations. Probable sources of impairment were impacts from abandoned mine lands and historic placer mining. The lower segment begins at the US 2 bridge and is impaired for sediment and siltation. Past activities have also impaired water quality in segments of the Fisher River, Rock Creek, and East Fork Rock Creek.

Suction dredging activities are currently permitted in the Libby Creek drainage. Monitoring by the KNF indicates limited sediment increases in the stream below dredging operations. At low flows, pools tend to accumulate sediment that is transported as bedload. Deposition of bedload would be more pronounced near the dredging sites. Unless substantial bank erosion occurs, increased sediment transport is limited because the overall sediment load delivered to the channel remains the same, and the effects downstream are probably minor (KNF 2007c). Other human activities that may impair surface water quality include septic field installation, livestock grazing, new roads, and other construction. Stream channel and bank stabilization or restoration projects may improve stream water quality.

The Miller-West Fisher Vegetation Management Project consists of commercial timber harvest, pre-commercial thinning and prescribed fire, access management changes, trail construction and improvement, treatment of fuels in campgrounds, and watershed rehabilitation activities in the Miller, Silver Butte, and West Fisher Creek watersheds. If timber harvest activities occurred during the transmission line construction, the two projects may cumulatively increase sediment in Miller Creek or West Fisher Creek over the short term, depending on the transmission line alignment. Road and access management, and watershed condition improvements proposed in the Miller-West Fisher Vegetation Management Project would minimize adverse cumulative effects on surface water quality. Stabilization of streambanks in West Fisher Creek and Montanore road closures in Alternatives C-R, D-R and E-R would cumulatively reduce sediment delivery in West Fisher Creek over the long term.

The proposed Wayup Mine in upper West Fisher Creek and the Libby Creek Ventures drilling plan adjacent to Upper Libby Creek Road would have negligible cumulative effect on water quality. The Montanore and Rock Creek Projects would cumulatively reduce streamflow in Rock Creek and East Fork Bull River. Mine dewatering and the resulting drawdown of bedrock groundwater may subtly change the water quality of the East Fork Rock Creek and East Fork Bull River.

3.13.4.11 Regulatory/Forest Plan Consistency

This section discusses compliance with applicable laws and regulations regarding changes in water quality. Section 3.11.4.10, *Regulatory/Forest Plan Consistency* in the previous *Surface Water Hydrology* section discusses compliance with laws and regulations regarding changes in streamflow and floodplains.

3.13.4.11.1 Organic Administration Act and Forest Service Locatable Minerals Regulations

The Forest Service is responsible for ensuring that mine operations on National Forest System lands comply with Forest Service locatable mineral regulations (36 CFR 228 Subpart A) for environmental protection. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources. 36 CFR 228.8 also requires that mining operators comply with applicable state and federal water quality standards including the Clean Water Act; comply with applicable Federal and State standards for the disposal and treatment of solid wastes; take all practicable measures to maintain and protect fisheries and wildlife habitat which may be affected by the operations; construct and maintain all roads so as to assure adequate drainage and to minimize or, where practicable, eliminate damage to soil, water, and other resource values; and reclaim the surface disturbed in operations by taking such measures as preventing or controlling onsite and off-site damage to the environment and forest surface resources.

The BPA's Sedlak Park Substation and loop line would be on private land and would not be subject to compliance under the Organic Administration Act and Forest Service locatable minerals regulations.

Minimize Adverse Environmental Impact (36 CFR 228.8)

Alternative 2 would have a disturbance area of 2,582 acres. The disturbance area of Alternative 4, which would have a tailings impoundment at the same location as Alternative 2, would be smaller than Alternative 2 by 658 acres by eliminating the LAD disturbance area and minimizing the disturbance area around the tailings impoundment. The disturbance area of Mine Alternative 3 would be the smallest. Because the clearing width for Transmission Line Alternative B would be narrower than the agencies' transmission line alternatives, the maximum clearing width for Alternative B would be less than the agencies' alternatives. Clearing associated with the agencies' transmission line alternatives would be minimized through the development and implementation of a Vegetation Removal and Disposition Plan. The agencies' transmission line alternatives would have less clearing and new road development in the watersheds of impaired streams, in watersheds of Class 1 streams, and on soils with severe erosion risk, high sediment delivery, and slope failure. The predicted delivery of sediment to project area streams from roads in the agencies' mine and transmission line alternatives would be less than in MMC's alternatives. All mine and transmission line alternatives would include the use of BMPs to minimize erosion and effects on surface water quality. The agencies' alternatives would include more frequent BMP monitoring than MMC's alternatives. In summary, Mine Alternative 2 and Transmission Line

Alternative B would not fully comply with 36 CFR 228.8 because MMC did not propose to implement feasible measures to minimize the disturbance area and adverse environmental impacts on surface water quality. Mine Alternatives 3 and 4 Transmission Line Alternatives C-R, D-R, and E-R would comply with 36 CFR 228.8 because the modifications to the disturbance area are feasible and would minimize adverse environmental impacts on surface water quality.

In Alternative 2, MMC proposed to use land application for its primary water treatment method. If land application of excess water resulted in BHES Order limit or nondegradation criteria exceedances, MMC would treat the additional water at the Water Treatment Plant instead of discharging it to the LAD Areas. The agencies' analysis of MMC's proposed plans for land application of excess water predicted, without additional primary treatment before land application, concentrations would be greater than BHES Order limits or applicable nondegradation criteria in groundwater beneath the LAD areas and in surface water in Ramsey, Poorman, and Libby creeks. The agencies' analysis also indicated that tailings water in Alternative 2 would reach surface water without pumpback wells. Any exceedances of BHES Order limits or applicable nondegradation criteria would not comply with state and federal water quality standards. MMC committed to implementing seepage control measures, such as pumpback recovery wells, if required to comply with applicable standards.

The agencies' mitigation in Alternatives 3 and 4 (using a water treatment plant for all discharges, modifying the existing treatment plant to treat nitrogen compounds (primarily nitrates and ammonia), phosphorus, and possibly dissolved metals, increasing the capacity of the existing treatment plant, and requiring a pumpback well system around the impoundment) would minimize changes in water quality in Libby Creek and eliminate changes in water quality of Ramsey and Poorman Creek. In Alternatives 3 and 4, the operation of the diesel generator at the mill site would not exceed 16 hours during any rolling 12-month time period after the electric transmission line was operational. Tier 4 engines and ultra-low sulfur diesel fuel also would be used in underground mobile equipment. These measures would minimize nitrogen and sulfur deposition into wilderness lakes. Alternative 2 would not fully comply with 36 CFR 228.8 because MMC did not propose to implement feasible measures to minimize adverse environmental impacts on surface water quality and fisheries habitat. Alternatives 3 and 4 would comply with 36 CFR 228.8 because the proposed water treatment modifications are feasible and would minimize adverse environmental impacts on surface water quality and fisheries habitat.

Ditches and sediment ponds that would contain process water or mine drainage would be designed in Alternative 2 for a 10-year/24-hour storm. In Alternatives 3 and 4, the ditches and sediment ponds would be designed for a 100-year/24-hour storm. The larger conveyance capacity would more likely capture all stormwater containing process water or mine drainage during the life of the project and would minimize water quality effects on east side streams and fisheries habitat.

In Alternatives 3 and 4, runoff from the reclaimed tailings impoundment would be directed toward Little Cherry Creek instead of Bear Creek proposed in Alternative 2. As part of the final closure plan, MMC would complete a H&H analysis of the proposed runoff channel during final design that would include a channel stability analysis and a sediment transport assessment. The runoff channel would be designed to minimize adverse effects of increased streamflow on Little Cherry Creek water quality and fisheries habitat.

Waste rock management would not comply with 36 CFR 228.8 in Alternative 2. Waste rock would be temporarily stored at an unlined area in the LAD Area 1, Libby Adit Site, and/or Ramsey Adit portal, or hauled to the tailings impoundment area and then used in the impoundment dam. In Alternative 2, the Ramsey Plant site would be constructed of waste rock and be sited in a RHCA. In Alternatives 3 and 4, waste rock would be stored temporarily in lined stockpiles, hauled to a lined location within impoundment footprint, and then used in impoundment dam. The Libby Plant Site in Alternatives 3 and 4 would not be built with waste rock and waste rock would be eliminated as a potential source of metals and nutrients in infiltration and surface water runoff. Alternatives 3 and 4 would comply with 36 CFR 228.8 because the proposed waste rock modifications are feasible and would minimize adverse environmental impacts on surface water quality and fisheries habitat.

State and Federal Water Quality Standards (36 CFR 228.8(b))

In Alternative 2, MMC proposed to use land application for its primary water treatment method. If land application of excess water resulted in BHES Order limit or nondegradation criteria exceedances, MMC would treat the additional water at the Water Treatment Plant instead of discharging it to the LAD Areas. MMC committed to implementing seepage control measures, such as pumpback recovery wells, in Alternative 2 if required to comply with applicable standards. The agencies' analysis of MMC's proposed plans for land application of excess water predicted, without additional primary treatment before land application, concentrations would be greater than BHES Order limits or applicable nondegradation criteria in groundwater beneath the LAD areas and in surface water in Ramsey, Poorman, and Libby creeks. The agencies' analysis also indicated that tailings water in Alternative 2 would reach surface water without pumpback wells. Any exceedances of BHES Order limits or applicable nondegradation criteria would not comply with state and federal water quality standards. Alternative 2 would have a greater risk of not complying with state and federal water quality standards than Alternatives 3 or 4.

The agencies' mitigation in Alternatives 3 and 4 (using a water treatment plant for all discharges, modifying the existing treatment plant to treat nitrogen compounds (primarily nitrates and ammonia) and possibly dissolved metals, increasing the capacity of the existing treatment plant, and requiring a pumpback well system around the impoundment) are designed to minimize changes in surface water quality in the Libby Creek watershed, eliminate changes to groundwater quality by avoiding land application, and ensure compliance with State and Federal water quality standards. The agencies' alternatives expanded MMC's proposed monitoring plans and would include action levels for specific parameters (see Appendix C). Compliance with state and federal water quality standards is discussed below under the Clean Water Act and the Montana Water Quality Act.

Solid Waste Disposal (36 CFR 228.8(c))

All mine and transmission line alternatives would comply with applicable Federal and State standards for the disposal and treatment of solid wastes. All mine alternatives would dispose of tailings and reclaim the tailings impoundment in a manner to minimize adverse impact on the environment and forest surface resources. All mine and transmission line alternatives would comply with the applicable portions of 36 CFR 228.8(c) regarding compliance with federal and state standards for solid waste and tailings disposal. In Alternative 2, MMC would occasionally bury certain wastes underground in mined-out areas. In the agencies' mine and transmission line alternatives, MMC would comply with Forest Service policies when disposing of demolition debris during closure. The agencies' transmission line alternatives would comply with the

Environmental Specifications (Appendix E) regarding solid waste disposal. It is Forest Service policy (FSM 2130) to discourage the disposal of solid waste on National Forest System lands unless such use is the highest and best use of the land. No solid wastes other than waste rock would be buried underground in mined-out areas. Reinforced concrete foundation materials may be buried on National Forest System lands only under certain conditions. These measures would minimize the impact on the environment and forest surface resources. The plans for waste disposal in the agencies' alternatives would comply with 36 CFR 228.8(c).

Fisheries and Wildlife Habitat (36 CFR 228.8(e))

The differences in water treatment methods between Alternative 2 and Alternatives 3 and 4 were discussed in the above section. The agencies' analysis of MMC's proposed plans for land application of excess water predicted, without additional primary treatment before land application, water quality concentrations would be greater than BHES Order limits or applicable nondegradation criteria in surface water in Ramsey, Poorman, and Libby creeks, which would adversely affect fisheries habitat. Alternative 2 would have a greater risk of not complying with 36 CFR 228.8(e) as it applies to water quality than Alternatives 3 or 4.

The above section discussed the differences in the disturbance area, clearing, road construction, and post-closure runoff from the impoundment between the MMC's alternatives and the agencies' alternatives. These modifications in the agencies' alternatives are practicable measures to maintain and protect fisheries. MMC's mitigation plans contained limited measures to protect fisheries habitat from changes in streamflow. The agencies' alternatives would create or secure genetic reserves through bull trout transplanting or habitat restoration; rectify factors that are limiting the potential of streams to support increased production of bull trout; and eradicate non-native fish species, especially brook trout that are a hybridization threat to bull trout.

Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8(e) because MMC did not propose to implement practicable measures to minimize adverse environmental impacts on surface water quality and fisheries habitat. Mine Alternatives 3 and 4 Transmission Line Alternatives C-R, D-R, and E-R would comply with 36 CFR 228.8(e) because the changes in disturbance area, clearing, road construction, and post-closure runoff from the impoundment are practicable and would minimize adverse environmental impacts on surface water quality and fisheries habitat.

Roads (36 CFR 228.8(f))

The following discussion applies to the requirements of 36 CFR 228.8(f) as they apply to surface water quality. Compliance with 36 CFR 228.8(f) regarding roads management is discussed in section 3.6.4.11.4, *National Forest Management Act/Kootenai Forest Plan* (RF-2 through RF-5), beginning on page 453.

In all mine and transmission line alternatives, roads would be constructed and maintained to ensure adequate drainage and to minimize or, where practicable, eliminate damage to soil, water, and other resource values. The Environmental Specifications describe how transmission line roads would be constructed and maintained to ensure adequate drainage and to minimize or eliminate damage to resource values. The agencies' transmission line alternatives would have less new road development in the watersheds of impaired streams, in watersheds of Class 1 streams, and on soils with severe erosion risk, high sediment delivery, and slope failure. The predicted delivery of sediment from roads to streams in the agencies' mine and transmission line alternatives would be less than in MMC's alternatives. At the end of operations, all mine and transmission line alternatives would have roads no longer needed for operations. The agencies' mitigation provides more specificity regarding management of roads no longer needed for operations. Such roads would be placed either in intermittent stored service or decommissioned. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8(f) as it relates to water quality because MMC did not propose to implement practicable measures to minimize adverse environmental impacts on surface water quality and fisheries habitat. Mine Alternatives 3 and 4 Transmission Line Alternatives C-R, D-R, and E-R would comply with 36 CFR 228.8(f) as it relates to water quality.

Reclamation (36 CFR 228.8(g))

The following discussion applies to the reclamation requirements of 36 CFR 228.8(g) as they apply to surface water quality. Compliance with 36 CFR 228.8(g) regarding reclamation requirements is discussed in section 3.19.4.6 under *Soils and Reclamation*, p. 872. All mine and transmission lines alternative would comply with the requirements of 36 CFR 228.8(g) regarding controlling erosion, controlling surface water runoff, and isolating toxic materials. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8(g) to implement practicable measures to prevent or control onsite and off-site damage to the environment and forest surface resources. MMC did not propose to implement practicable measures to minimize erosion and maximize reclamation success. The agencies' alternatives would include developing and implementing a final Road Management Plan and a Vegetation Removal and Disposition Plan; increasing the salvage and replacement of suitable soil materials for reclamation; removing a majority of coniferous forest debris removed before soil removal; consolidating soil stockpiles and reclaiming them incrementally; and salvaging disturbed wetland soils for use in constructing new wetlands. These measures would minimize erosion and ensure reclamation success. The agencies' alternatives would comply with 36 CFR 228.(g) as it relates to water quality.

3.13.4.11.2 Clean Water Act and Montana Water Quality Act

The Forest Service is responsible for ensuring that mine operations on National Forest System lands comply with Forest Service locatable mineral regulations (36 CFR 228 Subpart A) for environmental protection. Operators must comply with applicable federal and state water quality standards, including regulations issued pursuant to the Clean Water Act. The DEQ is responsible for ensuring all mine operations comply with the Montana Water Quality Act and its implementing rules.

The BPA is responsible for ensuring construction and operation of the Sedlak Park Substation and loop line comply with the Clean Water Act and the Montana Water Quality Act. Construction and operation of the Sedlak Park Substation and loop line would comply with the Clean Water Act and the Montana Water Quality Act. The BPA would prepare and implement a SWPPP during substation and loop line construction to minimize water erosion.

The above section discussed the differences in disturbance area, clearing, road construction, and post-closure runoff from the impoundment between the MMC's alternatives and the agencies' alternatives. The modifications in the agencies' alternatives are practicable measures to reduce nonpoint source pollution. All mine and transmission line alternatives would include the use of BMPs to minimize erosion and effects on surface water quality. The agencies' alternatives would include more frequent BMP monitoring than MMC's alternatives. All mine and transmission line alternatives would comply with the USDA Nonpoint Source Water Quality Policy Directive 9500-007.

In Alternative 2, MMC proposed to use land application for its primary water treatment method. If land application of excess water resulted in BHES Order limit or nondegradation criteria exceedances, MMC would treat the additional water at the Water Treatment Plant instead of discharging it to the LAD Areas. MMC committed to implementing seepage control measures, such as pumpback recovery wells, in Alternative 2 if required to comply with applicable standards. The agencies' analysis of MMC's proposed plans for land application of excess water predicted, without additional primary treatment before land application, concentrations would be greater than BHES Order limits or applicable nondegradation criteria in groundwater beneath the LAD areas and in surface water in Ramsey, Poorman, and Libby creeks. The agencies' analysis also indicated that tailings water in Alternative 2 would reach surface water without pumpback wells. Any exceedances of BHES Order limits or applicable nondegradation criteria would not comply with the Clean Water Act or the Montana Water Quality Act. Any tailings water reaching surface water would not comply with the ELGs promulgated under Clean Water Act. Alternative 2 would have a greater risk of not complying with the Clean Water Act or the Montana Water Quality Act than Alternatives 3 or 4.

The agencies' mitigation in Alternatives 3 and 4 (using a water treatment plant for all discharges, modifying the existing treatment plant to treat nitrogen compounds (primarily nitrates and ammonia), phosphorus, and possibly dissolved metals, increasing the capacity of the existing treatment plant, and requiring a pumpback well system around the impoundment) are designed to minimize changes in water quality in Libby Creek, eliminate changes in water quality of Ramsey and Poorman Creek, eliminate changes to groundwater quality at the LAD areas, and ensure compliance with the Clean Water Act and the Montana Water Quality Act. The agencies' alternatives expanded MMC's proposed monitoring plans and included action levels for specific parameters (see Appendix C).

The DEQ will discuss compliance with applicable water quality regulations including the ELGs and nondegradation rules in the ROD and the Statement of Basis for the MPDES permit renewal. Unless the DEQ waives its issuance, a 401 certification from the Montana DEQ would certify that MMC's proposed discharges of fill permitted under a Section 404 permit are in compliance with all applicable water quality requirements of the Clean Water Act. Unless the 401 certification is waived, the mining operator must give a copy of the 401 certification to the Forest Service before the KNF would authorize MMC to commence any activity that requires a 404 permit.

36 CFR 228.8(h) states that "certification or other approval issued by state agencies or other federal agencies of compliance with laws and regulations relating to mining operations will be accepted as compliance with similar or parallel requirements of these regulations." DEQ's permit decision and associated conditions on the MPDES permit renewal, DEQ's decision and associated conditions on the 401 certification, and any other state water quality permit would constitute compliance with Montana water quality requirements and Clean Water Act requirements regarding water quality.

3.13.4.11.3 Kootenai Forest Plan

Alternative 2 would have a greater risk of not comply with the KFP than Alternatives 3 or 4. The agencies' analysis of MMC's proposed plans for land application of excess water indicated they would result in water quality standard exceedances without additional pretreatment. The agencies' analysis also indicated that tailings water in Alternative 2 would reach surface water without pumpback wells. Alternative 2 would have a greater risk of exceeding water quality standards than Alternatives 3 or 4. In Alternatives 3 and 4, all water would be treated at a water treatment plant before discharge and would be required to meet water quality standards. All mine and transmission line alternatives would comply with the KFP standard to use soil and water conservation practices and BMPs to minimize nonpoint source pollution. The agencies' alternatives would include more frequent BMP monitoring than MMC's alternatives.

3.13.4.12 Irreversible and Irretrievable Commitments

Water quality impacts resulting from mine inflows post-mining would be an irreversible commitment of surface water resources.

3.13.4.13 Short-Term Uses and Long-Term Productivity

Any change in stream water quality due to discharging mine water to area streams would be a short-term use of the resource. Changes that may occur that would affect the long-term productivity of surface water resources in terms of water quality are water quality changes that may occur due to loss of deep groundwater supply to streams, springs, and lakes.

3.13.4.14 Unavoidable Adverse Environmental Effects

If less groundwater were contributed to Rock Lake, the lake total dissolved solids, silica (needed by diatoms), and nutrient concentrations may decrease in the lake.

3.14 Geotechnical Engineering

This section discusses the lead agencies' analysis of the risk of subsidence in the underground mine, and the stability of the tailings impoundment for Alternatives 2 and 4 (Little Cherry Creek) and Alternative 3 (Poorman). Also included in this section is a comparison of the two alternative tailings sites.

3.14.1 Analysis Area and Methods

Subsidence as related to mining is the downward displacement of the ground surface resulting from the collapse of underground mine workings. The vertical displacement and areal extent of the surface subsidence is related to the size of the underground mine void, its depth below the ground surface, and the area over which the underground collapse has occurred. For this analysis, the area for the subsidence evaluation is the area overlying the Montanore ore body.

Current subsidence prediction and evaluation methods depend on past experience and observed behavior from historical subsidence events. One approach examines the ability of the in place rock to remain stable over a mined-out void, or conversely stated, determining under what conditions rock will fail and collapse into the mined void. This analysis method is suitable for chimney-type failures where the failure process is confined to a relatively narrow chute and the resulting surface subsidence is manifested by sinkholes. MMC used this approach in their subsidence evaluation (Call & Nicholas, Inc. 2005a) by examining the ability and likelihood for there to be sustained caving of rock between the underground workings and the ground surface, which if occurs, would result in subsidence. This analysis method is often used in the design of mines dependent on caving as the ore extraction technique. The lead agencies evaluated the results of MMC's analysis for chimney subsidence, but used a different approach by determining whether the underground pillars were adequately sized to prevent collapse of the underground workings (Agapito Associates, Inc. 2007b). If enough of the pillars fail, the excess weight transferred to adjacent pillars can cause a chain-reaction of pillar failure known as cascading pillar failure. Cascading pillar failure frequently results in surface subsidence over a far greater area (trough subsidence) than what is generated by a chimney-type failure. Evaluating whether mine pillars are adequately sized is also a commonly used technique in underground mine design.

In addition, the agencies performed a Failure Mode and Effects Analysis (FMEA) following methods used by Klohn Crippen (1998, 2005) for the Rock Creek Project to assess the risk of subsidence. The FMEA took into account Troy Mine subsidence experience. Because of similarities between the Montanore and Rock Creek projects, the Rock Creek Project underground mine FMEA is pertinent to the Montanore Project as well.

The analysis area for the impoundment stability analysis is Little Cherry Creek in Alternatives 2 and 4, and between Poorman and Little Cherry creeks in Alternative 3. Klohn Crippen (2005) updated the original design of the proposed Little Cherry Creek tailings impoundment and all associated facilities, incorporating new data on seismicity, ground conditions and seepage parameters since the NMC design from the 1990s, and making design changes required by the lead agencies in their 1992 project approvals. The lead agencies developed a design for an alternative Poorman Tailings Impoundment Site between Poorman and Little Cherry creeks in Alternative 3 in sufficient detail to analyze its effects in the EIS.

3.14.2 Affected Environment

3.14.2.1 Seismicity and Seismic Hazard

The analysis area is located at the northern end of the Intermountain Seismic Belt, which extends from southern Nevada northward through Utah and eastern Idaho and western Montana. In western Montana, the Intermountain Seismic Belt is up to 62 miles wide. The Intermountain Seismic Belt is characterized by moderate to large earthquakes with shallow focal depths. The vast majority of historical seismic activity within western Montana has been concentrated along the Intermountain Seismic Belt (Klohn Crippen 2005)

The seismic analysis for the tailings impoundment employed a deterministic approach by using a known active fault as the source of the seismic event, assigning an earthquake magnitude, and calculating a resulting ground motion at the tailings impoundment site. Five faults identified as being potentially active in the last 1.6 million years are located within 50 miles of the impoundment sites. The closest known potentially active fault to the analysis area is the Bull Lake Fault, located about 12 miles west of the project site. The Bull Lake Fault was used to estimate the site seismicity and is summarized in Table 133 (Klohn Crippen 2005). The site is located in a moderately active seismic area. The design maximum credible earthquake (MCE) is a potential Magnitude 7.0 earthquake on the Bull Lake Fault, which results in a peak ground acceleration of 0.22 g. The fault is part of a series of northwest-southeast trending faults, although the activity along the fault is uncertain. Larger faults, which typically are associated with larger seismic events, are located farther away and do not control the design seismicity. The Bull Lake Fault is unlikely to affect any of the transmission line alignments or the Sedlak Park Substation and loop line.

Table 133. Maximum Credible Earthquake and Site Seismicity.

Parameter	Value
Magnitude (M)	M7.0
MCE Assumed Epicentral Distance	12 miles (19 km)
Source	Bull Lake Fault, classified as later Quaternary, <700,000 years old and potentially active
Peak Bedrock Acceleration (average from attenuation relations)	0.22 g(*) (average from attenuation relations)
Duration of Significant Shaking	27 seconds

*g = gravitational acceleration (32.2 ft/sec^2).
Source: Klohn Crippen 2005.

3.14.2.2 Avalanches and Landslides

Numerous avalanche chutes occur in both upper Libby Creek and Ramsey Creek valleys. The only facility within an avalanche chute path is the Libby Adit Site (Figure 48). Three avalanche chutes are near the Libby Adit Site. The Upper Libby Adit Site, proposed in Alternative 3, is between two avalanche chutes. Because of the high elevation of the chute tops and the narrow widths of the valleys below, avalanches can cross valleys and move up the opposite side.

No landslides or unstable slopes were identified near mine facilities, along the transmission line alignments, or near the Sedlak Park Substation and loop line. Fine-grained soils derived from glaciolacustrine silts and clays are susceptible to slope failures if undercut. Section 3.19.3.1.2, *Glaciolacustrine Soils* discusses these soils in more detail.

3.14.3 Environmental Consequences

3.14.3.1 Subsidence

3.14.3.1.1 Alternative 1 – No Mine

No mining would occur; therefore, the potential for mining-related subsidence would not be present. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150, would remain in effect. The DEQ's approval of revisions to DEQ Operating Permit #00150 (Minor Revisions 06-001 and 06-002) also would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that do not affect National Forest System lands. Potential subsidence from the Libby Adit would be mitigated by backfilling the entire adit length that occurs in unconsolidated bedrock.

3.14.3.1.2 Alternative 2 – MMC's Proposed Mine

Summary

The lead agencies' evaluation (Agapito Associates, Inc. 2007b) concluded that chimney subsidence breaching the surface to form sinkholes is unlikely given the geotechnical setting (thickness of the overlying rock above the mine workings, and the strength of the overlying rock) and the mine plan proposed by MMC. Isolated roof failure and chimney subsidence to some height above the workings is likely, and could lead to increased rock fracturing and higher groundwater hydraulic conductivity within the overlying strata. The evaluation also estimated that chimney subsidence impacts on groundwater may occur up to about 400 feet above the mine workings. The agencies' evaluation concluded that trough subsidence, while not likely, cannot be entirely dismissed at the current level of design.

Introduction

Underground mining causes a redistribution of stress, which in turn causes displacements in the affected strata. Subsidence is the result of downward displacement of the rock mass from closure or collapse of underground openings. The terms "subsidence" and "surface subsidence" are generally used interchangeably; subsidence has the potential to affect groundwater where it is encountered, even where subsidence has not progressed to the surface.

The magnitude and extent of mining-induced subsidence are directly related to the type and extent of the mining activity. In partial-extraction mining (such as the room-and-pillar method proposed for the Montanore Project), rock strength is estimated and pillars are sized and left permanently to support the overburden, so that subsidence is not planned to occur during active mining. The complex interaction of rock strength, zones of structural weakness, local and regional tectonic forces, and gravity make accurate projections on the likelihood of subsidence very difficult. A stable underground environment during the mining process, could over time become unstable due to some triggering event or changed ground condition. Subsidence after mine abandonment due to time-dependent pillar, roof, or floor failure may still occur and may be the dominant form of subsidence in room-and-pillar mining even in the absence of secondary pillar recovery (Singh 1992). Further, residual subsidence may occur tens or even hundreds of years after active mining (Thorburn and Reed 1977; Mahar and Marino 1981). It is difficult to know if and when conditions will change sufficiently to initiate collapse of underground workings which could lead to surface subsidence.

The two major modes of subsidence associated with mining are chimney subsidence and trough subsidence. Chimney subsidence is associated with roof collapse over small areas, such as individual drifts (Figure 77). Mining through structural weaknesses zones such as a faults can trigger and increase the height of chimney subsidence. Two chimney subsidence events that resulted in sinkholes at the Troy Mine have been reported (Tetra Tech and R Squared 2006). The collapsing rock strata cave progressively upward toward the surface in a chimney-like fashion until either the increased volume of the caved material arrests cave progression, or caving breaches the surface. If chimney subsidence breaches the surface, a sinkhole is formed. Trough subsidence, in which a subsidence basin is formed above caved and sagging strata, occurs over larger areas (*e.g.*, many acres) and is associated with wide-scale pillar, roof, or floor failure.

Geologic Setting

The ore deposit at Montanore occurs in two nearly parallel zones within the lower Revett Formation, part of the Belt Supergroup. The average thickness of the Zone 1 is 30 feet and Zone 2 averages 34 feet. A barren lead zone, ranging in thickness from 0 to 200 feet and averaging about 30 feet, separates the two ore zones. The ore body lies on the lower limb of an overturned syncline (Figure 63) that plunges to the northwest. The syncline is bounded to the west by the Rock Lake Fault, a steeply dipping normal fault, and to the east by the Libby Lake Fault. Ore body dip follows the northwest plunge of the syncline, and ranges from about 5° to 50°. Dimensions of the ore body are about 2,000 feet wide by 11,000 feet long. The thickness of the unmineralized zone overlying the ore body ranges from zero (0) feet at the outcrop at Rock Lake to about 3,800 feet near Libby Lakes (Agapito Associates, Inc. 2007b). Most of the ore body is overlain by between 2,000 and 3,500 feet of cover.

The lower Revett Formation consists primarily of quartzite with some siltite and silty quartzite beds. In addition to the Revett Formation, overlying rocks belong to the St. Regis and Wallace formations. The St. Regis Formation consists of siltites and argillites with some quartzite. The Wallace Formation consists of argillite, siltite, limestone, and dolomitic quartzite. Additional information about the geology of the mine area is found in section 3.9, *Geology and Geochemistry.*

Several lakes exist over or adjacent to the ore body, including Rock Lake on the extreme southern end of the deposit (the ore body outcrops beneath and near Rock Lake), St. Paul Lake on the northern end, and the Libby Lakes near the eastern boundary. Additional information about the surface water resources in the mine area is found in section 3.11.3, *Affected Environment.*

Two other economic copper/silver deposits exist in the general vicinity of the Montanore Project. The Troy Mine (Spar Lake deposit) was permitted in 1979 and was in production until 1993. In late 2004, the Troy Mine was brought back into production. In December 2012, Revett suspended all underground mining activities following back and pillar failures in both the north and south ore bodies in the Middle Quartzite of the Revett Formation that manifested as surface cracking and shallow subsidence (Call & Nicholas 2014). The Rock Creek Project is west of the Montanore Project; the KNF currently is conducting additional environmental analysis of the project (see section 3.3.2.1, *Rock Creek Project*). Although the lithology and mineralogy of the ore zones of the Spar Lake, Rock Lake and Rock Creek deposits are similar, there are significant differences in the character of the sediments overlying the deposits (Tetra Tech, Inc. and R

Squared Incorporated 2006). Continental glaciation in the vicinity of the Troy Mine has resulted in unconsolidated sediments up to 70 feet thick, whereas the Rock Lake and Rock Creek deposits typically has little unconsolidated sediment overlying the bedrock.

MMC's Plan to Minimize Subsidence

MMC has indicated that pillar and opening dimensions would be designed with the goal of preventing surface subsidence. Spans of about 40 feet to 45 feet are planned. A pillar design study (Call & Nicholas 2005a) recommended 62-foot-long pillars, 40-foot-wide openings, and pillar widths varying from 19.5 feet to 49 feet, including 2 additional feet of both width and length to compensate for blast damage. These pillar widths were based on the Wilson pillar design approach (Wilson 1972) and a 1.3 safety factor. Required pillar widths would increase with cover depth (the amount of rock overlying the mine) and pillar height. The Call & Nicholas pillar design study provided for a cover range of 1,000 feet to 3,800 feet. As part of the Libby Adit Evaluation Phase, MMC would conduct additional underground core drilling before developing final mine plans. The drilling would be used to collect detailed information on underground geologic structures, ore thicknesses, ore grades, and hydrology. MMC did not explicitly eliminate the possibility of secondary recovery, or "pillar robbing," at the end of mining, which, if conducted, would increase subsidence risk. Any change to the final mine plan would require the agencies' approval. Additional information about MMC's mine plan is discussed in section 2.4.2.1*, Mining*.

To reduce possible subsidence risk and the interception of groundwater in the potential subsidence area, MMC plans to observe a 500-foot vertical and horizontal buffer zone where the mineralized ore horizon outcrops near Rock Lake. In addition, a 100-foot barrier pillar is planned as a buffer to the Rock Lake Fault. It is anticipated that additional developmental drilling would better define the fault zone and, thus, the limit of mining near the fault and lake. MMC may use a narrower barrier, but only with the agencies' prior approval, should additional testing determine that a smaller buffer zone would be adequate to protect against subsidence and/or hydrologic disturbance. Alternately, the additional testing may indicate that a larger buffer zone would be necessary and MMC would be required to stay farther from the fault or lake.

Potential for Chimney Subsidence, and Likely Effects Were it to Occur

Due to the depth of cover over the mine workings and the high strength of the rock overlying the mining horizon, it is unlikely that chimney subsidence would breach the surface to form sinkholes (Agapito Associates, Inc. 2007b). Some roof failure at mine level would be likely over time, especially after mine abandonment. Caving propagation (incremental upward movement) to some height above the workings would likely occur, but the strength of the overlying rock and the magnitude of the *in situ* tectonic forces likely would lead to the formation of a stable arch of rock over the collapsed area. Should such caving occur, MMC's estimates of final cave height are between 150 feet and 380 feet, or 2.1 to 5.4 times the assumed maximum 70 feet mining height (Call & Nicholas 2006). Due to the thickness of rock overlying the Montanore ore body, and the buffers proposed by MMC, these cave heights would not breach the surface. Any groundwater intercepted by the caved strata would be rapidly transmitted to the mine workings. A fractured zone with increased hydraulic conductivity may exist for some distance above the caved zone, but given the likely diameter of the caved zone (a few feet to tens of feet), the thickness of the fractured zone would be limited and not likely to reach the surface based on the amount of rock overlying the ore. No other direct impacts are anticipated should chimney subsidence occur.

Two chimney subsidence events that resulted in sinkholes at the Troy Mine have been reported (Tetra Tech and R Squared 2006). As discussed in 3.9, *Geology and Geochemistry*, the mineralogy of the ore zone at the Troy Mine is similar to that of Montanore. Sinkhole #1 was initially observed in October 1997 (Call & Nicholas 2005b), about 4 years after the mine had been shut down. At that time, the sinkhole was about 8 feet deep and 15 feet in diameter. By spring 2005, the sinkhole had increased to about 50 to 55 feet deep and 50 feet in diameter. At the mine level, material from the East Fault, a north-northwest trending normal fault that dips at about 65° to the northeast, had accumulated in two separate drifts sometime between the mine closing in 1993 and spring of 2005. Based on measurements of the accumulation of fault material in the mine, estimation of the sinkhole volume, estimates of fault gouge bulking factors, spatial relationships between the East Fault and the mine workings, and other factors, Call & Nicholas (2005b) concluded that the sinkhole was probably not related to underground excavation.

A second sinkhole formed in February 2006, and both sinkholes #1 and #2 were analyzed by Tetra Tech and R Squared (2006). Sinkhole #2 was about 135 feet long and 100 feet wide, with a depth between 20 and 30 feet. It was first noticed 4 days after a ground failure and cave in the underground workings of the Troy Mine. Based on projections of the East Fault to the surface, the location of the sinkholes relative to these projections, and on calculations regarding swell factor and chimney size, Tetra Tech and R Squared concluded that the sinkholes were mining related. The structurally weak East Fault acted as a conduit for progressive rock failure. The overlying rock in and next to the fault was so highly broken, fractured and degraded that it lacked sufficient inherent strength to form a stable arch.

While relevant to the analysis of subsidence potential at Montanore, the formation of sinkholes above the Troy Mine does not imply a similar risk of sinkhole formation at Montanore. The mining depths associated with the two Troy sinkholes were 270 feet and 320 feet, respectively (Tetra Tech and R Squared 2006). Minimum mining depth at Montanore would be 500 feet. Assuming similar mining heights, the increased depth at Montanore would reduce the likelihood of sinkhole subsidence, as would MMC's plan to leave a 100-foot horizontal buffer between mining activity and the Rock Lake Fault. No such plan was required at the Troy Mine, where the East Fault was routinely approached and/or penetrated as part of the mining operation. Had a mitigation plan similar to the Montanore plan been in place at the Troy Mine, it is unlikely that sinkhole subsidence would have occurred (Agapito Associates, Inc. 2007b).

Potential for Trough Subsidence, and Likely Effects Were it to Occur

MMC's design calls for stable pillars to be left in place. If the design assumptions were met, trough subsidence and associated impacts would not occur. Any change to the final mine plan would require the agencies' approval. In order to quantify worst-case impacts, the remaining discussion in this section assumes that design assumptions were not met, and that trough subsidence occurred.

Based on published data from historical incidences of subsidence, trough subsidence over the workings due to unforeseen roof, pillar, or floor failure may result in maximum surface subsidence of 0.1 to 0.2 times the 70 feet mining height, or 7 feet to 14 feet. Surface subsidence would be much less than this if the width of failure at mine level were less than about 1.4 times the cover depth (Agapito Associates, Inc. 2007b). In this case, subsidence at the surface may be minimal or visually undetectable. If substantial surface subsidence were experienced, it would be measured over a surface area that somewhat approximates the area affected at mine level. The area affected at mine level is defined by the draw angle, the angle, in section, measured from the vertical, between the edge of the mine workings and the point on the surface at which subsidence is not detectable. A negative draw angle results in an affected surface area smaller than the area of failure, whereas the opposite is true for a positive draw angle. Based on case studies of initial draw angles in caving operations, it is estimated that the draw angle could vary from -12° to 28°. Using the latter as a worst-case scenario at maximum cover, subsidence could be measured for horizontal distances up to 2,000 feet beyond the footprint of failure. Surface damage is not likely to occur over the full angle of draw, but over the angle of critical deformation, which is typically about 10° less. Therefore, surface subsidence effects may occur up to 1,200 feet beyond the footprint of failure, based on an angle of critical deformation of 18°.

Following back and pillar failures in both the north and south ore bodies in the Middle Quartzite of the Revett Formation that manifested as surface cracking and shallow subsidence, the KNF required Revett to evaluate the pillar design and mining methods used at the Troy Mine to aid in the determination of the causes and contributing factors leading to ground subsidence. Call & Nicholas, Inc. prepared an analysis of subsidence and ground fall at the Troy Mine (Call & Nicholas 2014). The KNF contracted an independent third party review of the Call & Nicholas report and related documents, and an independent evaluation of the Troy Mine subsidence through back-analysis of pillar safety factors (Agapito Associates, Inc. 2014b). In addition, the KNF and the DEQ contracted review of information related to recent surface subsidence observed above the Troy Mine in the context of implications to the Montanore Project (Agapito Associates, Inc. 2014a).

The Call & Nicholas (2014) describes the history of instability associated with middle and lower quartzite mining at the Troy Mine. Before the 2012 failures, no surface subsidence was observed. In 2012, an undetermined number of pillars failed west of the main drive in the north ore body, and a progressive pillar and back collapse was initiated. Access to the area was completely cut off and a full assessment of the damage was not possible. Call & Nicholas investigated surface subsidence and reported that “the surface subsidence observed indicates that the back and pillar failures in both the [north ore body] and [south ore body] of the Middle Quartzite were insufficiently bulked shut by caved material before the down-dropped block,…was undercut and allowed to move along several surface expressed faults. While some portion of the closure was accommodated by separation of bedding, the remainder was expressed as surface subsidence.”

If design assumptions were not met and trough subsidence occurred, surface resources that may be affected include wildlife and vegetation, wetlands, and visual quality. Assuming this worst-case scenario, the lead agencies evaluation concluded the potential for impacts on these resources would be low (Agapito Associates, Inc. 2007b). The referenced report explains the conclusion in more detail.

Possible Effects on Groundwater

Subsidence has the potential to affect groundwater where it is encountered, even where subsidence has not progressed to the surface. Chimney or trough subsidence would have the potential to affect surface water and groundwater in several ways and the effects of subsidence on the hydrologic regime can be highly variable and complex. Numerous case studies have been presented in the literature, and conflicting conclusions between studies are common (Peng 1992). The major factors controlling subsidence effects on hydrology include the horizontal and vertical distance between the caved zone and the water resource and the hydrologic properties of the intervening strata. The severity of hydrologic damage decreases with distance from the subsidence and the presence of low permeability stratum. Peng (1992) suggest an angle of influence of 16° to 26° is appropriate for estimating the distance beyond which hydrologic resources should be unaffected.

Within the angle of influence, hydrologic effects are expected to vary according to where water resources were intercepted vertically. If unplanned trough subsidence occurred, rapid transmission of any groundwater to the workings is expected in the caved zone, for a distance of 2 to 8 times the mining height, or 140 feet to 560 feet, assuming a total mining height of 70 feet (Agapito Associates, Inc. 2007b). A fractured zone would exist over the caved zone, extending perhaps 1,400 feet to 2,100 feet above the mine workings. Increased permeability would be associated with the fractured zone, and permeability would increase from the top of the fractured zone downward. Above the fractured zone, surface fissures may develop, but they probably would not to extend to the fractured zone, as tensile stresses would likely die out and become compressive at some distance beneath the surface. Groundwater flows may be affected from the surface to the fractured zone; any such interruption would continue until post-mining hydraulic heads stabilize.

As previously discussed, the caving height associated with chimney subsidence is estimated between 150 feet and 380 feet, or 2.1 to 5.4 times the assumed maximum 70 feet mining height (Call & Nicholas 2006). Groundwater within this zone would be transmitted to the workings. Increased permeability above this zone would exist, although the zone of increased permeability would likely be of limited extent. The effect on groundwater hydrology is discussed in section 3.10.4.2.1*, Evaluation through Operations Phases*.

The potential for chimney or trough subsidence would be largely a function of mine design and the condition of the rock surrounding the underground workings. MMC has proposed collecting additional underground geotechnical data as part of its Libby Adit evaluation program. The evaluation program would provide additional data to assess local ground conditions, subsidence potential, pillar sizing requirements to minimize the risk of trough subsidence, and the potential of fractures above the mine workings to affect groundwater.

3.14.3.1.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative and Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Alternative 3 and Alternative 4 would have the same risk of subsidence and are discussed together. MMC would undertake additional measures regarding pillar design, structural setting, interaction of mine voids and pillars in the two ore zones, and roof support analyses to finalize room and pillar dimensions and the ground support plan. MMC would use a minimum 0.8 pillar width to height ratio as a preliminary numeric criterion, to be finalized during later design efforts, and subject to KNF and DEQ approval. These measures are described under Alternative 3, section 2.5.2.5.4 *Final Underground Mine Design Process*. In addition, the agencies' mitigation of increasing the buffer zones near Rock Lake and the Rock Lake Fault, and the agencies' monitoring, described in Appendix C, coupled with final design criteria submitted for the agencies' approval, would minimize the risk of subsidence and associated effects on surface resources in the CMW.

Agapito Associates' back-analysis of pillar safety factors (Agapito Associates, Inc. 2014b) led to the development of three key mitigation measures designed to minimize subsidence risk:

- Use a variety of pillar strength estimation approaches such as Obert and Duvall (1967), Wilson (1972), Hedley and Grant (1972), Hardy and Agapito (1975), Bieniawski (1981), Stacey and Page (1986), Abel (1988) and Esterhuizen *et al.* (2008) to calculate pillar strength and corresponding factor of safety. This would allow the agencies to better evaluate the MMC design in relation to other standard approaches.
- Use a minimum 0.8 pillar width to height ratio as a preliminary numeric criterion (Agapito Associates, Inc. 2014b). Pillars with less than a 0.8 width to height ratio would require justification by MMC as to their stability.
- Explicitly assess sill pillar stability during all mine planning phases.

MMC would submit a final subsidence monitoring plan to the agencies for approval following the completion of the Libby Adit evaluation program. The most valuable geotechnical data are obtained during mining itself. A rock mechanics program that includes the agencies' mitigations on pillar design, structural geology, interaction between workings, and entry stability and support would reduce the potential for trough subsidence. A comprehensive underground drilling and mapping program would identify zones of structural weakness, such as faults, which could be avoided thereby reducing the potential for triggering a chimney type failure.

The KNF completed a FMEA of the Rock Creek Project underground mine, taking into account the Troy Mine experience, and developed mitigations as part of agency-modified alternatives (Agapito Associates, Inc. 2014a, 2014b). The KNF concluded for the Rock Creek Project that the risks of all failure modes identified during the FMEA for the underground mine, after applying compensating factors, were low or inconsequential. No high or moderate risk failure modes were identified. Because similar compensating factors considered in the FMEA of the Rock Creek Project underground mine would be incorporated into the Montanore mine plan, the agencies concluded the risks of subsidence at Montanore also would be low or inconsequential. The plans and mitigations for Montanore are discussed in section 2.5.2.5.4 *Final Underground Mine Design Process*.

Effectiveness of Agencies' Proposed Mitigation Measures in Alternatives 3 and 4

The agencies' mitigation for subsidence, described in section 2.5.2.5.4, *Final Underground Mine Design Process*, the agencies' mitigation of increasing the buffer zones near Rock Lake and the Rock Lake Fault, and the agencies' monitoring, described in Appendix C, coupled with final design criteria submitted for the agencies' approval, would effectively minimize the risk of subsidence and associated effects on surface resources in the CMW. In addition to the agencies' mitigation measures and monitoring, MMC would fund and facilitate biannual surveys of the underground workings that would be completed by an independent qualified mine surveyor. MMC also would fund an independent technical advisor to assist the agencies in review of MMC's subsidence monitoring plan, underground rock mechanics data collection, and mine plan. Based on the agencies' mitigation and monitoring measures and funding of independent technical assistance during all phases of the project, the agencies conclude the risk of subsidence would be less than in Alternative 2.

3.14.3.2 Impoundment Stability

3.14.3.2.1 Alternative 1 – No Mine

The risk of an impoundment failure and associated impacts would not exist. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150, would remain in effect. The DEQ's approval of revisions to DEQ Operating Permit #00150 (Minor Revisions 06-001 and 06-002) also would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that do not affect National Forest System lands.

3.14.3.2.2 Alternative 2 – MMC's Proposed Mine and Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

The impoundment design in Alternative 2 would be the same as Alternative 4, and both alternatives are discussed together. Through the rest of this section, the impoundment design and analysis is referred to only as the Alternative 2 design or impoundment. In Alternatives 3 and 4, MMC would implement the final design process described in section 2.5.2.5, *Final Design Process.* Technical review of the final tailings facility design would be made by a technical advisory group established by the KNF described in the same section.

The tailings impoundment dam in all alternatives would be considered by the DNRC as a high-hazard dam. The DNRC classifies a dam as high-hazard if it impounds more 50 acre-feet and the DNRC determines that a loss of human life is likely to occur within the flooded area as a result of failure of the dam. The hazard classification is based on the potential loss of life downstream and is not an assessment of the safety of the structure. Dams under a DEQ Operating Permit are exempt from Montana's Dam Safety Act.

MMC used commonly accepted industry criteria and standards for dam design and construction for this point in the design process. The origin and basis of the criteria are founded in years of geotechnical engineering research, design, construction, and performance monitoring. These criteria are set and followed by the U.S. Corps of Engineers (2003) and U.S. Bureau of Reclamation (1977) and serve as the design standards for State dam safety rules and regulations. The same standards also apply to soil and rock structures such as waste rock stockpiles, and cut and fill slopes.

Site Seismicity

The estimated Peak Ground Acceleration (PGA) of 0.22 g (Table 133) is sufficient to demonstrate the feasibility of providing dynamic stability in the layout and design of the tailings impoundment. The site seismicity would be re-evaluated during final design to ensure the estimated PGA is the most appropriate value for the Montanore site and for construction of a high-hazard dam. The PGA is the maximum rate of ground motion that will occur at a site. In MMC's analysis, PGA was based on occurrence of the maximum credible earthquake (Table 133).

Morrison-Knudsen Engineers completed the original seismicity assessment for the project in 1990 (Morrison-Knudsen Engineers 1990). Morrison-Knudsen Engineers' estimated PGA value was the median (middle) probabilistic value obtained from several procedures used to estimate ground motion attenuation. In its update, Klohn Crippen confirmed the appropriateness of Morrison-Knudsen Engineers' PGA value. The estimated PGA value is based on a given probability that a seismic event of a certain magnitude would occur at the site. If the probability of occurrence is changed, a new PGA is determined at the site. Generally, a higher probability of occurrence of an earthquake along a given fault results in a lower magnitude of earthquake and a lower PGA at the site. A deterministic PGA value (a selected PGA value based on the upper range of estimated ground accelerations regardless of the probability (percent chance) of the event occurring and impacting the site) may be more appropriate for the Montanore tailings impoundment. This approach is consistent with seismic design guidelines for tailings dams (International Commission on Large Dams (1989) and the United States Committee on Large Dams (1999) (recommended design criteria by Klohn Crippen (2005)).

The design guidelines proposed by MMC (Klohn Crippen 2005) set the basis for a safe design and construction of the tailings impoundment. The references and agency guidelines cited by MMC, including the DNRC's dam safety regulations, do not provide specific standards with respect to seismic stability of large, high-hazard dams. The agencies' mitigation in Alternatives 3 and 4 would include incorporation of guidelines from other states, as appropriate, during final design.

Stability

MMC addressed the stability of the tailings impoundment dams through a series of minimum allowable safety factors against failure for static and dynamic loading conditions of the facilities (Klohn Crippen 2005). The factors of safety (FOS) for stability are summarized in Table 134. In addition, MMC completed a qualitative risk assessment of potential causes of failure of the tailings facility (Klohn Crippen 2005).

Included in the stability evaluation was a liquefaction analysis (the potential for a soil to act as a heavy fluid with little or no shear strength) to determine the locations of liquefiable or potentially liquefiable ground during the MCE of M7.0. The analysis was based on the number of hammer blows required to drive the soil sampler one foot (blow counts or 'n' values) obtained from Standard Penetration Tests (SPT) recorded during the different geotechnical work conducted in the Little Cherry Creek drainage basin. Under the Little Cherry Creek Tailings Impoundment Main Dam foundation area, the soils with SPTs that were found to indicate potentially liquefiable foundation materials are generally near the ground surface. The liquefaction assessment found that most of the foundation materials under the Alternative 2 tailings Main Dam are medium dense to dense. Only isolated pockets of material have the potential to liquefy during seismic loading with little or no impact on dam stability if left undisturbed during dam construction. Foundation materials under a portion of the Diversion Dam are loose to medium dense and could control the stability of the dam. The influence of the potential liquefaction zones was considered in the stability analyses for the Diversion Dam in Alternative 2 (Klohn Crippen 2005).

Liquefaction of the glaciolacustrine clay beneath the Main Dam foundation would be very unlikely due to the high fines content (*i.e.*, >30%), but could occur under the right conditions. Large seismic events can be expected to generate elevated pore pressures in the clay and could produce a short-term loss of strength following the seismic event (Klohn Crippen 2005). The location of a clay layer within the foundation beneath the right (south) abutment of the Starter Dam and its potentially low shear strength characteristics make the presence of the clay in the foundation a concern with respect to the design and stability of the tailings impoundment Main Dam. As a precaution, MMC proposes to remove a portion of the clayey material and backfill with compacted fill to act as a "shear key" for stability (Figure 9). A shear key is an area of backfilled and compacted material beneath a dam to enhance resistance against the dam sliding horizontally along a preferred plane and to increase the shear resistance of the material under the embankment thereby inhibiting the formation of a circle failure plane. Based on preliminary design, up to three shear keys may be required under the final dam footprint. The extent of the glaciolacustrine clay and its strength would be assessed during final design to determine how much of the material would be removed and to optimize the location and dimensions of shear keys. Similar materials have not been identified in the foundation of the Poorman tailings dam

Table 134. MMC Design Criteria and Calculated Values for Factor of Safety for Alternatives 2 and 4 Impoundment.

Loading Condition	Standard	Minimum Allowable Design Value	Calculated Value
Static Loading Condition	Limit-Equilibrium Factor of Safety (FOS)	FOS = 1.5 For operations and closure. FOS = 1.3 For end-of-construction conditions†.	2.06 1.8
Maximum Credible Earthquake (MCE)	Limit-Equilibrium FOS (Pseudo-static)	FOS = 1.15 For operating and end-of-construction conditions†.	1.34 1.17
	Displacements Estimated by Pseudo-Static Stability Analyses	Horizontal displacement of dam toe = 10 feet. Vertical settlement at the ultimate dam crest limited to less than 3 feet to prevent release of tailings.	2.5 to 10 feet Not Available
Post-Earthquake	Limit Equilibrium Factor of Safety	FOS = 1.1 Using residual strength in liquefied tailings and glaciolacustrine clay.	1.18
	Dynamic Deformation Analysis	Assessment using Makdisi-Seed, and Hynes-Griffith and Franklin empirical methods, as cited in Klohn Crippen 2005.	2 to 10 feet (horizontal)

†End-of-construction stability generally refers to completion of a compacted earthfill dam, not a cycloned sand dam as construction would be ongoing. Values reported are for cyclone dam at end of 5 years of operation. End-of-construction FOS for the compacted starter dam and saddle dams are not available.
Source: Klohn Crippen 2005.

site, but geotechnical data are limited and would need to be expanded to confirm suitability of the dam foundation materials and stability of the dam.

The MCE earthquake estimated for the project site probably would not cause the tailings to liquefy and result in a catastrophic failure. As discussed in section 3.9, *Geology and Geochemistry*, the tailings at the proposed Montanore Mine are likely to be similar to the tailings at the Troy Mine. The tailings at Troy were found to be dilatant (Knight-Piesold and Co. 2007). A dilatant material (also termed shear thickening) is one in which viscosity (commonly perceived as "thickness," or resistance to flow) increases with the rate of shear.

MMC's design criteria (Table 134) outlined the stability evaluation techniques and set the target FOS values to be used. Operational performance and dam safety depend upon on the quality of the geotechnical data and the correct application and use of industry accepted design procedures to complete the design and estimate the FOS. For this reason, thorough geotechnical field studies and complete laboratory test programs are essential in achieving a safe dam structure. The more reliable the available data, the fewer and less conservative are the assumptions for unavailable or unknown design information. Data that is less reliable or available increase the assumptions and the conservatism required to achieve a safe design. Critical conditions have been evaluated and conservative assumptions have been made regarding foundation conditions and strength parameters. Based on the data presented by Klohn Crippen (2005), it has been demonstrated that a safe tailings dam structure could be constructed for Alternatives 2 and 4 with respect to meeting the minimum allowable FOS design criteria based on currently available data. Based on the stability analyses and estimated FOS values for the tailings impoundment dam, the Main Dam would be stable and not exhibit signs of distress or failure. The analyses presented by Klohn Crippen (2005) adequately demonstrate the feasibility of constructing, operating and reclaiming a stable tailings dam under Alternative 2. Additional geotechnical field and laboratory tests would be needed to address assumptions made in the preliminary design and confirm the stability of the dam. In Alternative 4, the seismic design parameters would be re-evaluated using more current data and evaluation procedures, and the dynamic stability confirmed based on any revised parameters. In addition, circular failure plane assessments through the near-dam tailings and dam section and through the dam crest and slope would be completed during final design of the dam.

Tailings slurry deposition patterns used in operations of the impoundment can influence tailings facility stability: the impoundment capacity, and tailings particle size segregation, which can influence the tailings consolidation characteristics. These two issues are not high risk items and normally not an influence in demonstrating the feasibility of a project. For the Little Cherry Creek site, the issues become important due to limited space for dam expansion beyond that proposed. In addition, changes in dam height and dam configuration to increase the impoundment capacity would be critical as it affects other design issues, such as the material mass balance for the cyclone sand dam. Dam stability could be affected should additional dam height be required to store the tailings. Tailings deposition patterns and settled density would be re-evaluated during final design.

Perimeter discharge of tailings slurry, as planned by MMC, typically results in tailings surfaces sloped downward toward the interior of the impoundment area. This downward slope of the tailings away from the embankment crest reduces the available capacity at a given height compared to capacity calculated assuming level tailings deposition. The current height-volume relationship for the Alternative 2 tailings impoundment site is based on level tailings deposition in the impoundment, with some freeboard allowance for the slope of the tailings surface (Klohn Crippen 2007). The agencies' analysis indicates that the height of the dam necessary to achieve the required tailings capacity would need to be slightly higher than the crest elevation estimated by Klohn Crippen. This in turn would require a modification to the dam design and a re-evaluation of the dam stability. Final determination of the dam height versus impoundment capacity would be based on tailings deposition plans and the proposed final end-of-operation surface grading plan. The final dam height and dam configuration would be detailed during final design to confirm the appropriate dam height for use in the final stability analyses.

Tailings deposition patterns into the impoundment also influence the dam height and ultimate stability should the average settled density be less than estimated. Larger particles settle nearest the discharge point and finer particles settle farther out as the tailings slurry flows away from the discharge point. Long travel distances from the point of discharge often result in particle segregation within the tailings impoundment, which typically results in a tailings mass that exhibits lower average settled densities and consolidation characteristics from what was achieved during laboratory testing. Densities lower than estimated may require additional dam height to provide the same storage capacity. Lower tailings densities may also impact the dam stability analyses when considering stability of the upstream section of the dam crest.

In the 1992 Montanore Project Final EIS, artesian groundwater conditions beneath the Little Cherry Creek impoundment site were discussed. Artesian pressures at both impoundment sites (Little Cherry Creek and Poorman) were identified in some boreholes during the site investigations conducted by NMC (Morrison-Knudsen Engineers, Inc. 1990). NMC proposed to use a system of pressure relief wells to relieve artesian water pressures. In 1992, the agencies concluded an adequately designed pressure relief well system would relieve artesian pressure and ensure dam stability during all project phases. MMC reviewed the hydrogeology and assessed the potential effects of the artesian pressures on the dam stability (Klohn Crippen Berger Ltd. 2008), and concluded:

- The stability of the downstream slope of the dam is controlled primarily by the soft glaciolacustrine clay, and the strength of the clay is controlled by the undrained shear strength
- The proposed downstream slope of the dam is flatter than the original design by Morrison-Knudsen
- The impoundment design includes an extensive underdrain system, which would limit the transfer of hydraulic head from the impoundment into the foundation soils
- Existing artesian pressures are not expected to become significantly higher due to impoundment construction and the artesian pressures would not affect the failure mode, including a failure plane through the glaciolacustrine clay
- The dam would be raised in stages over the life of the mine and piezometric pressures in the foundation would be monitored

The agencies concurred with MMC’s conclusions regarding artesian pressures based on available data. In addition, MMC would install pumpback recovery wells in Alternatives 3 and 4 to collect tailings seepage not intercepted by the Seepage Collection System. The pumpback recovery wells would be located beyond the dam toe, and would be designed to collect seepage not collected by the drain system. The pumpback well system would reduce artesian pressures beneath both impoundment sites in Alternatives 3 and 4. The foundation design would be confirmed as part of the final design studies.

Failure Modes Effects Analysis

In addition to completing stability analyses to verify that the design criteria FOS would be met for the tailings dam, MMC completed a qualitative risk assessment of the Little Cherry Creek impoundment using a modified Failure Mode and Effects Analysis (FMEA) process (Klohn Crippen 2005). The agencies updated the analysis in 2008 to include all project infrastructure in Alternatives 2 and 3 (Klohn Crippen Berger 2009). The FMEA is an engineering reliability technique used to systematically identify, characterize, and screen risks that derive from the failure of an engineered system to operate or perform as intended. The term “risk” encompasses the concepts of both the likelihood of failure (the expected frequency of failure), and the severity of the expected consequences if such events occurred. FMEA seeks to characterize risks in a systematic way and is intended to identify the main risks or failure modes (McLeod and Plewes 1999). Because predictive risk assessment involves foreseeing the future, it is an imprecise art (Robertson and Shaw 2003).

An assessment of likelihood and consequences of failure for construction, operations, and closure was made for each of the design and operational components. Five issues were included in the 2008 FMEA related to the tailings dam stability: 1) higher than predicted pore pressure in glaciolacustrine clays; 2) higher than predicted uplift groundwater pressure; 3) loose glacial outwash layer liquefying under seismic loading; 4) plugging of dam underdrains increasing pore pressures; and 5) plugging of impoundment underdrains increasing pore pressures(Klohn Crippen Berger 2009).

The FMEA was completed in a sequential manner by identifying the following:

1. Likelihood of failure quantified on a five-level scale based on an annual probability of failure/percent chance of occurrence (>50%, 10-50%, 1-10%, 0.1-1%, and <0.1%)
2. Consequences of failure ranked on a five-level scale (insignificant to catastrophic) for four areas (water quality, biophysical, community-social, and costs)
3. Level of confidence in the likelihood of failure and/or the consequences based on a three-level scale of high, moderate, and low
4. Compensating factors to reduce the risk for each failure mode and effect

The factors were compared and a Level of Risk was determined for each failure mode. The Level of Risk ranged from Level 5 (completely unacceptable) to Level <1 (lowest level of risk). Each Level of Risk was identified by a pairing of likelihood of an occurrence with consequences of the occurrence. As the Level of Risk decreased, the possibility of occurrence/outcome pairings that resulted in that Level of Risk increased, as summarized below.

- Risk Level 5 – A likelihood of "always certain" and "catastrophic" consequences
- Risk Level 4 – Likely occurrence and catastrophic consequences to always certain occurrence and major consequences
- Risk Level 3 – Possible occurrence and catastrophic consequences to always certain likelihood and moderate consequences
- Risk Level 2 – Unlikely occurrence and catastrophic consequences to always certain likelihood and minor consequences
- Risk Level 1 – Conceivable but improbable occurrence and catastrophic consequences always certain occurrence and insignificant consequences
- Risk Level <1 – Inconsequential risks

Of the failure modes evaluated in 2008 for the Little Cherry Creek impoundment, three were judged to have a risk level of 2, and the other modes had a risk level of 1 or less. The identified Level 2 risks and associated management strategies are shown in Table 135.

Table 135. Level 2 Risks of Little Cherry Creek Tailings Impoundment Site.

Risk	Management Strategy
Loose glacial outwash layer liquefies under seismic loading, leading to dam failure.	Dam design to assume that some material could liquefy. Additional site investigations would better define the spatial extent of any loose layers (see section 2.5.2.5, *Final Design Process*).
"Pervious" soil connection between tailings and bedrock aquifer. "Unknown" aquifer connection to former Little Cherry Creek.	Install pumpback wells to intercept seepage. Install wells downstream of tailings facility for monitoring seepage collection and groundwater quality. Analyze tailings water balance and track seepage return flow to estimate seepage discharging into groundwater (see section C.10.5.5, *Water Balance* in Appendix C).
Erosion due to extreme precipitation on closure.	Closure design to reduce risk of erosion with riprap in potential high flow areas. Long-term care and maintenance would provide for potential repairs after extreme events (see discussion of long-term site monitoring and maintenance in section 1.6.3.2.3, *Other Reclamation Costs*).

Source: Modified from Klohn Crippen Berger 2009.

3.14.3.2.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Stability

The lead agencies completed a stability evaluation of Alternative 3. The purpose was to confirm the feasibility to locate and design a stable Poorman Tailings Impoundment facility at a 120 million-ton capacity between Little Cherry and Poorman creeks.

Design criteria for minimum FOS values for static and dynamic loading conditions were the same as set for the Alternative 2 impoundment site. The PGA value used in the pseudo-static analysis was assumed to be the same as Alternative 2. The two sites (Alternatives 2 and 3) are adjacent to one another and based on limited drilling information from the Poorman site (Alternative 3) appear to have similar foundation conditions. In addition, Alternative 3 borrow soils and cyclone sand foundation materials were assumed to be similar to the Alternative 2 materials; therefore, the Alternative 2 strength parameters were used in the stability analysis. In some cases, lower values were used in the analysis as a degree of conservatism because site-specific data for Alternative 3 are limited and Alternative 3 would be a critical facility to the project. The strength parameters for the tailings were slightly increased to a friction (phi) value equal to 20° because Alternative 3 tailings would be deposited as a high-density slurry resulting in a denser (*i.e.*, higher strength) in-place product. Tailings placed as a high-density slurry generally show an increase in shear strength parameters over tailings placed at a lower slurry density (Klohn Crippen 2005).

The stability of the Alternative 3 tailings dam was evaluated using the slope stability computer program STABL developed at Purdue University. The use of the STABL program is widely accepted in the dam design/geotechnical industry as a suitable design tool, as is the Slope/W program used by Klohn Crippen for the Alternative 2 stability analysis. Both programs incorporate the same methods of analyses in estimating the FOS of a slope. Several commercial software programs that incorporate the STABL program are available. The commercially available software XSTABL 5.0 was used to facilitate data input and view plots of the most critical surfaces (lowest FOS) determined in the analyses. Potential failure surfaces were searched for within the downstream sections of the dam and tailings impoundment, and through the embankment crest and tailings on the upstream side of the dam. In addition, the stability of the tailings slope deposited from the back of the impoundment and above the dam crest elevation was checked to assess the feasibility of placing the tailings in such a configuration. Based on the results of the analyses, the Alternative 3 tailings facility can be designed as a safe and stable structure under both static and pseudo-static loading conditions. Table 136 presents a summary of the results.

Table 136. Calculated Values for Factor of Safety for Alternative 3 Impoundment.

Case	Static FOS	Pseudo-Static FOS	Post-Earthquake FOS
Average Strength Parameters			
Cyclone Sand Dam Minimum allowable FOS	1.9 (1.5)	1.4 (1.15)	1.4 (1.1)
Upper Tailings Slope Minimum allowable FOS	- (1.5)	1.8 (1.15)	2.7 (1.1)
Reduced Strength Parameters			
Cyclone Sand Dam Minimum allowable FOS	1.5 (1.5)	1.1 (1.15)	1.3 (1.1)
Upper Tailings Slope Minimum allowable FOS	5.4 (1.5)	1.5 (1.15)	1.8 (1.1)

Source: Glasgow Engineering 2008.

The tailings deposited from the back slope of the impoundment area and at an elevation above the constructed embankment crest elevation would create the most critical situation for instability in Alternative 3. This situation was evaluated in the stability analyses completed for Alternative 3 (Glasgow Engineering 2008). Based on the results of the analyses presented in Table 136, the proposed cyclone dam and tailings slope would be stable under static and pseudo-static loading conditions and post-earthquake strength reductions. In all but one case, the minimum FOS was met or exceeded in the analyses. The one case that did not meet the minimum was the pseudo-static analysis of the cyclone sand dam assuming reduced shear strength values. The estimated FOS was greater than 1.0 (*i.e.*, not indicating a likely slope failure), but was lower than the minimum allowable FOS. Impacts of failure of the tailings slope would be similar to liquefaction of the tailings slope as discussed in the following paragraph.

Liquefaction potential of the tailings slope deposited at the rear of the impoundment was not considered in the stability review, although recently deposited tailings are subject to liquefaction. The volume of the liquefied mass located at the rear of the impoundment is critical to impoundment stability only if the available storage volume within the impoundment at the dam crest elevation were less than the volume of the liquefied tailings *and* if all of these liquefied tailings were to move *en* masse as a uniform debris flow from the back of the impoundment, down into the impoundment area, and towards the dam. This would not be a critical issue until near the end of the Year 16 of operations. At the end of Year 16, mud wave action from the liquefied tailings and displacement of water stored in the impoundment could result in the overtopping of the embankment crest and possible breach of the dam. This potential for release of tailings from the impoundment may be the most critical situation related to Alternative 3. Such a failure mode has not been quantified but should be included in the final design of the facility. The primary mitigation measure would be increased dam freeboard above the storage level of the tailings. This situation would be most critical in the later years of operations, as it is possible that tailings would not be stored very far above the dam crest until after Year 10 of operations.

The issues of discharge patterns and tailings consolidation patterns related to the dam stability are less influential than as described under Alternative 2. The anticipated slope of the thickened tailings was considered in the conceptual layout of Alternative 3. Also, thickened tailings would not "flow" out into the impoundment in the same manner as slurried tailings. In-place particle segregation and changes in consolidation characteristics are typically not as critical with thickened tailings as with slurry.

Failure Modes Effects Analysis

The Poorman site has a very similar risk profile as the Little Cherry Creek site. Some of the risks differed because of use of more complex technology (thickened tailings), uncertainty of foundation conditions, and proximity to private land. Of the failure modes evaluated for the Poorman Impoundment, six were judged to have a risk level of 2, and the other modes had a risk level of 1 or less. The Level 2 risks identified for the Little Cherry Creek impoundment site would apply to the Poorman site. The additional Level 2 risks and associated management strategies identified for the Poorman Impoundment Site are shown in Table 137.

Table 137. Additional Level 2 Risks of Poorman Tailings Impoundment Site.

Risk	Management Strategy
Pore pressure in clay requires flatter slopes and less storage capacity.	Site investigation would be carried out (see 2.5.2.5, *Final Design Process*)
Foundation more permeable than predicted affects local landowner and require more seepage control.	Site investigations would be carried out and the design modified to reduce seepage. Groundwater monitoring wells and pumpback wells would be installed and monitored during the Construction, Operations, and Closure Phases.
Deposited densities less than predicted requiring more storage capacity.	Test tailings during final design process (see agencies' testing requirements in section 2.5.2.5, *Final Design Process*). Plant operations may require additional backup systems (see prior discussion in the *Operation Flexibility and Impoundment Expansion Potential* section.

Source: Modified from Klohn Crippen Berger 2009.
These risks are in addition to those presented for Little Cherry Creek in Table 135.

Effectiveness of Agencies' Proposed Mitigation Measures in Alternatives 3 and 4

Section 2.5.2.5, *Final Design Process,* describes the process that MMC would use to complete final design of the tailings impoundment in Alternative 3. The design process would likely include a preliminary design phase and a final design phase. Site information would be collected during field studies during final design. The impoundment site in Alternative 4 likely has been sufficiently characterized and geotechnical field studies in Alternative 4 would be limit.

During final impoundment design in Alternatives 3 and 4, MMC would update the seismic stability analysis using the most recent attenuation relationships, update the pumpback well design and analysis, and avoid or minimize to the extent practicable filling waters of the U.S. or locating facilities in a floodplain. MMC would fund an independent technical review of the final design as determined by the lead agencies. Technical review of the final tailings facility design would be made by a technical advisory group established by the lead agencies. The tailings technical advisory group (TAG) would be comprised of agency experts in geotechnical, geochemical, and water quality issues related to current practices in the construction, operations, and closure of tailings facilities. The TAG would advise on the development of the quality assurance/quality control protocols for the tailings facility. The tailings TAG would also advise the lead agencies as to whether the environmental impacts associated with final design remained within the scope of those impacts identified in the Final EIS. The agencies' mitigation would be effective in ensuring the safe design and construction of a tailings impoundment that minimizes environmental impact.

3.14.3.3 Little Cherry Creek (Alternatives 2 and 4) and Poorman (Alternative 3) Tailings Site Comparison

This section presents a comparison of Little Cherry Creek (Alternatives 2 and 4) and Poorman (Alternative 3) tailings impoundment sites. The intent is to provide a summary of available data in each alternative in a comparative format. In general, the Poorman site was developed to avoid or minimize several environmental impacts of Alternative 2.

The primary technical difference in tailings disposal in Alternatives 2 and 3 is the method of tailings deposition used in each alternative. Alternative 2 is based on cyclone separation of the coarse fraction of the tailings for use in dam construction followed by slurry deposition of the finer fraction of the tailings into the impoundment area. Alternative 3 is based on cyclone separation of the coarse fraction of the tailings for use in dam construction as in Alternative 2, and then thickening of the retained finer grained portion of the tailings before deposition in the impoundment. The tailings would be thickened to increase the average in-place density of the tailings thereby reducing the required impoundment capacity.

The following sections present a comparison of the two alternatives based on data and information presented in Chapters 2 and 3, and MMC's Plan of Operations (MMI 2005a, MMC 2008). The comparison is divided in technical issues identified during the analysis process of the two alternatives. The data for each issue are presented in a summary format with brief discussions provided only as needed to clarify the comparison.

3.14.3.3.1 Site Capacity and Expansion Potential Tailings Deposition

Tailings Production

- Alternative 2 – Primary and secondary cyclone for sand generation and use in dam construction; 55 percent slurry density deposited into impoundment from primary cyclone overflow. Direct deposition of secondary cyclone overflow into the impoundment. Tailings surface slope at 1 to 1.5 percent average.
- Alternative 3 – Primary and secondary cyclone for sand generation and use in dam construction; thicken slurry density of primary and secondary cyclone overflow to a 70 percent slurry density at deposition into impoundment. Tailings surface slope at 3 to 5 percent.

120 million ton Capacity Requirement

- Alternative 2 impoundment capacity is reported by MMC as 115 to 120 million tons for a level tailings surface. Tailings discharge patterns into the impoundment have not been configured for a sloped tailings surface and is subject to reduction of total capacity at the proposed dam crest elevation. The net capacity has not been confirmed at 120 million tons.
- Alternative 2 Tailings Deposition – Slurry tailings at 55 percent solids by weight with an average density at the end of operation of 75 pcf (pounds per cubic foot). Deposition of thickened tailings was not considered necessary unless final design studies showed higher density tailings were required to maintain the proposed dam and impoundment footprint.
- Alternative 3 capacity is 120 million tons with thickened tailings deposition from a higher elevation along the back of the impoundment and a sloped tailings surface.
- Alternative 3 Tailings Deposition – Thickened tailings at 70 percent solids by weight with an average settled density of 85 pcf. Deposition of slurry tailings at 55 percent solids by weight was not considered practical as the tailings volume corresponding to this density would require an additional 15 feet of dam height. The ability to achieve these densities is discussed in the following *Operation Flexibility and Impoundment Expansion Potential* section.

Dam Construction

- Alternative 2 – Requires a Starter Dam, a North Saddle Dam, a ridge line South Saddle Dam later raised with cyclone sand, and a Main Dam constructed with cyclone sand (Figure 8).
- Alternative 3 – Requires a Starter Dam, a Rock Toe Berm to anchor toe area of main sand dam, an earthfill Saddle Dam, and a Main Dam constructed with cyclone sand (Figure 26).

Foundation Conditions and Borrow Material

- Alternative 2 – Foundation conditions generally good except that glaciolacustrine clay in Main Dam foundation potentially affects dam design. A portion of the clay would be excavated and backfilled with compacted fill to act as a shear key for stability. High groundwater level in Main Dam area. Sufficient borrow materials available within facility footprint and adjacent areas. Granular materials available through commercial sources. The volume of cyclone sand available for dam construction per year based on yearly production rates versus required volume of sand to raise the dam annually to maintain adequate storage capacity in the impoundment area has not been generated to date by MMC.
- Alternative 3 – Foundation conditions generally good and similar to Alternative 2. Glaciolacustrine clay may not be present in foundation; additional geotechnical investigations would be required. High groundwater level in Main Dam area. Sufficient borrow materials available within facility footprint and adjacent areas. Granular materials available through commercial sources. The volume of cyclone sand available for dam construction per year based on yearly production rates would meet required volume of sand to raise the dam annually to maintain adequate storage capacity in the impoundment area based on the proposed dam layout and impoundments operations. The annual dam volumes were interpolated from dam sections generated from raises at 40-foot height increments.

Seepage Control

- Alternative 2 – Seepage control in Alternative 2 would be provided primarily by collection drains in the impoundment and the dam foundation. The estimated seepage loss to groundwater is 25 gpm into the foundation footprint. Additional design components to reduce seepage losses would include an increased density of the impoundment drainage system, a pumpback well system between the dam and Seepage Collection Pond, or a deeper cutoff trench below the starter dam and under the saddle dams. Seepage interception would be facilitated by the cross-valley dam design. Seepage interception would be more difficult south of the South Saddle Dam, which would be immediately adjacent to the Diversion Channel. A coarse-textured paleochannel under the impoundment may capture and transmit more tailings water seepage than modeled in the seepage analysis.
- Alternative 3 – Seepage control in Alternative 3 would be similar to the Alternative 2 design for seepage control. It is assumed that the average seepage loss would be about 25 gpm as in Alternative 2. The potential for additional seepage control is similar to Alternative 2 and would employ the same alternatives. Due to the wide footprint of the dam face the Poorman Impoundment Site would require a more extensive seepage collection system. In addition, there would be less room downstream of the dam footprint to install a pumpback well system or other seepage interception systems between the dam toe and private property not owned by MMC.

Operation Flexibility and Impoundment Expansion Potential

- Alternative 2 – Upsets in daily operations such as pump failures and surges in the tailings system could likely be handled or accommodated without problems or threat of breach because of excess storage capacity in the tailings impoundment, and options for redirecting water and/or tailings to other storage facilities. An operating plan would address occurrences such as excess water build up or reduction in available cyclone sand. Generation of tailings slurry at 55 percent by weight is a commonly achieved density for tailings using the milling process proposed for Montanore. Less dense slurry deposition could occur due to improper design of the thickener or pumping system, temporary upsets in operations or improper operation practices. Such upsets are expected to be infrequent and short-term and should not affect the operation (water balance and storage capacity) of the impoundment. If extra impoundment capacity were needed, expansion of impoundment capacity beyond the proposed layout would require modifications in the design and construction of the dam crest. The perimeter area for extending the toe of the dam and continuing raises per design to increase capacity is very limited beyond the proposed footprint. Potential alternatives for dam crest raises would include over-steepening the downstream slope in subsequent raises or designing a modified upstream raise of the crest.

- Alternative 3 – Upsets in the tailings thickeners and in daily operations would require an operating plan to accommodate short periods of conventional (less dense) slurried tailings deposition within the impoundment. Such occurrences could be handled and include short-term increases in the amount of water sent to the impoundment with the tailings. The system required to thicken fine tailings to a slurry density of 75 percent has not been determined, but currently available thickening systems have achieved this density. The Montanore ore body consists of hard, unaltered rock that would be crushed to a fine-grained non-plastic material, which is generally amendable to thickening without the use of filters. The thickening system best suited for Montanore tailings would be determined before final design of the site was initiated. Once a system was determined feasible, the potential for upsets would be minimized and limited to infrequent and short-lived upsets as in Alternative 2. In the event it is demonstrated that the tailings could not be thickened in a reasonable manner, the suitability of Alternative 3 tailings facility would have to be re-evaluated and compared to Alternative 2. Expansion of impoundment capacity beyond the proposed layout would require modifications in the original design or in the design and construction of the dam crest sometime after operations began. The perimeter area for extending the toe of the dam and continuing raises per design to increase capacity is limited beyond the proposed footprint. Potential alternatives for dam crest raises would include over-steepening the downstream slope in subsequent raises or designing a modified upstream raise of the crest. Depending upon the characteristics of the thickened tailings, upstream deposition patterns and discharge elevations could also be modified to increase storage capacity.

Based on these comparisons, both alternatives have equally positive as well as limiting attributes and characteristics. The single significant difference between the two alternatives appears to be the ability to deposit the finer fraction of the tailings as a slurry at 55 percent solids by weight in Alternative 2 versus the likely necessity to deposit the tailings as a thickened tailings at 75 percent solids by weight in Alternative 3. This due to limits on the available impoundment footprint area at the Poorman Creek site. A secondary difference is that the storage capacity in Alternative 2 has not been confirmed relative to deposition patterns and the preferred tailings surface configuration at closure. The impoundment capacity in Alternative 3 was based on specific deposition patterns and a defined final tailings surface configuration. Another secondary difference between the alternatives is the potential for additional seepage control once in operation. Alternative 2 site conditions are likely better suited for the installation of remedial mechanisms or facilities for seepage control and collection than in Alternative 3 because of there being more room available for the installation of collections systems downgradient of the embankment toe. Additional design studies are required for both alternatives before identifying a preferred alternative based on technical comparisons such as those presented above. The difference in expansion potential for the two sites is negligible, based on the available data and site layouts.

3.14.3.4 Cumulative Effects

None of the reasonably foreseeable future actions would result in cumulative effects of subsidence risk or impoundment stability with the Montanore Project.

3.14.3.5 Regulatory/Forest Plan Consistency

The KFP does not have specific goals, objectives, and standards for subsidence and impoundment stability. It does contain goals, objectives, and standards for the CMW. All mine alternatives have the potential to indirectly affect wilderness qualities. Mitigation measures identified in Chapter 2 for Alternatives 3 and 4 and monitoring required for Alternatives 3 and 4 (Appendix C) would be implemented to minimize changes in wilderness character. In Alternatives 3 and 4, potential subsidence affecting wilderness lakes and wilderness character would be minimized by the agencies' mitigation described in section 2.5.2.5.4, *Final Underground Mine Design Process*. Key mitigation measures include:

- Completing pre-mine surficial topographic survey and geologic mapping of lands overlying the mine area to identify structures that could affect subsidence potential;
- Using a variety of pillar strength estimation approaches to calculate pillar strength and corresponding factor of safety; using a minimum 0.8 pillar width to height ratio as a preliminary numeric criterion and providing a justification for pillars with less than a 0.8 width to height ratio as to their stability;
- Explicitly assessing pillar stability during all mine planning phases; identifying two barrier pillars 20 feet wide across the width of the ore body that would be left in place (except for openings needed for access) during the first 5 years of mining until additional refinement of the hydrologic model was completed and the need for barrier pillars was evaluated;
- Maintaining at least a 1,000-foot buffer from Rock Lake and a 300-foot buffer from the Rock Lake Fault;
- Maintaining during mining a 100-foot buffer from identified faults unless the agencies approved a narrower buffer;
- Keeping the size and number of drives through the identified faults to the minimum necessary to achieve safe and efficient access across the fault unless the agencies approved a narrower buffer; and
- Explicitly stating that no secondary mining (reduction in pillar width or length, or increase in pillar height from designed final dimensions) would be allowed.

Mitigation measures and monitoring requirements in Alternatives 3 and 4 are reasonable stipulations for protection of the wilderness character and are consistent with the use of the land for mineral development. Alternatives 3 and 4 would be conducted to protect the surface resources in accordance with the general purpose of maintaining the wilderness unimpaired for future use and enjoyment as wilderness, and to preserve the wilderness character consistent with the use of the land for mineral development and production in compliance with 36 CFR 228.15 and the Wilderness Act. The agencies' mine and transmission line alternatives would comply with the Wilderness Act. Alternatives 3 and 4 would minimize adverse environmental impacts on surface resources within the wilderness, and thereby comply with the regulations (36 CFR 228, Subpart A) for locatable mineral operations on National Forest System lands.

3.14.3.6 Irreversible and Irretrievable Commitments

This section is not applicable to geotechnical engineering.

3.14.3.7 Short-term Uses and Long-term Productivity

This section is not applicable to geotechnical engineering.

3.14.3.8 Unavoidable Adverse Environmental Effects

Some roof failure would occur in all action alternatives.

3.15 Land Use

3.15.1 Regulatory Framework

3.15.1.1 Kootenai Forest Plan

The KFP guides all natural resource management activities and establishes management standards for the KNF (USDA Forest Service 1987a). The KFP establishes management direction in the form of prescriptions consisting of goals, objectives, standards, and guidelines. This direction may be established to apply throughout the forest plan area (forest-wide direction), or it may be established for only a part of the forest plan area, a Management Area (MA). The Montanore Project is being evaluated under the 1987 KFP. The KNF is undergoing a forest plan revision in cooperation with the Idaho Panhandle National Forest. The revision is not completed and the direction provided by the 1987 KFP is applicable to the Montanore Project. Management direction for the land use analysis area is described in section 3.15.3.2*, Kootenai National Forest Land Management Plan* below.

3.15.1.2 Montana Fish, Wildlife, and Parks/Plum Creek Conservation Easement

The FWP holds a conservation easement on some lands owned by Plum Creek where the transmission line may be located. Under the terms of the conservation easement, the FWP has reserved the right to prevent any inconsistent activity on or use of the land by Plum Creek or other owners and to require the restoration of any areas or features of the land damaged by such activity or use. Activities and uses prohibited or restricted include installing any natural gas or other pipelines or power transmission lines greater than 25-kV unless the prior written approval is given by the FWP.

3.15.1.3 Local Plans

Unincorporated Lincoln County has no comprehensive or general plan, zoning regulations, or growth policies.

3.15.2 Analysis Area and Methods

3.15.2.1 Analysis Area

The analysis area for land use encompasses an area with a 2,000-foot buffer surrounding project facilities: along the Bear Creek Road south from US 2, the proposed permit boundary areas for the mine facilities, the area crossed by the four transmission line alternatives and associated access roads, and the Sedlak Park Substation site and loop line area (Figure 78).

3.15.2.2 Methods

MMC's mine permit application (MMI 2005a, MMC 2008) contained information about land use in the mine area. In 2005, MMC completed a land use inventory for the transmission line corridors that MMC analyzed by reviewing, refining, and updating existing data (Power Engineers 2005c). The KNF provided digital data on the distribution of MAs on National Forest System lands. The KFP provided management prescriptions for each MA by resource, including recreation, wildlife and fish, timber, soils, water, and air resources, minerals and geology, lands, and facilities (USDA Forest Service 1987a).

The effects analysis assessed how the transmission line and mine facilities may alter existing land uses on both private and public lands within the land use analysis area. The changes in land use in the mine area were calculated based on the acreage of each permit area, and a 100-foot wide road corridor along the Bear Creek Road (NFS road #278), which is outside of a permit area.

In the 1993 ROD approving the lead agencies' preferred alternative for NMC's proposed Montanore Project, the KNF amended the KFP and reallocated an area surrounding the Little Cherry Creek Impoundment Site and the Ramsey Plant Site to MA 31. MA 31 is designed to accommodate the activities associated with mineral development on the KNF (USDA Forest Service 1993). All areas currently proposed for disturbance at the Ramsey Plant Site and the Little Cherry Creek Impoundment Site were not previously reallocated to MA 31, due to mapping technology and a slight change in the Little Cherry Creek Tailings Impoundment design from that approved in 1993. In Alternatives 2, 3 and 4, the KNF would amend the KFP by reallocating to MA 31 all areas within the permit areas of the plant site, the tailings impoundment, and LAD Areas 1 and 2 that currently are not MA 31. In addition, a proposed road and facility corridor that would cross MA 13 would be reallocated to MA 31. This amendment would apply only to National Forest System lands disturbed by any mine alternative, and would not apply to private lands affected by the mine alternatives. Maps showing areas of proposed reallocation are available at the KNF. Changes to existing MA designations were calculated for project facilities in each alternative.

The changes in land use in the transmission line corridors were calculated based on the acreage within a 150-foot tree clearing width for monopoles (Alternative B) and a 200-foot width for H-frame structures (for other alternatives except for a short segment of the West Fisher Creek Alternative that has monopoles). Actual acreage cleared would be less and would depend on tree height, slope, and line clearance above the ground. Acreage of new roads and roads with extensive upgrading requirements was based on an assumed total disturbance width of 25 feet.

Similar to the mine area, the KNF amended the KFP in the 1993 ROD and reallocated areas crossed by the selected North Miller Creek transmission line classified as "corridor avoidance" areas (224 acres) to MA 23. MA 23 is designed to accommodate the activities associated with electrical transmission corridors on the KNF (USDA Forest Service 1987a). All areas currently proposed for disturbance by MMC's proposed transmission line alignment classified as corridor avoidance areas were not reallocated to MA 23 due to mapping technology and slight changes in the North Miller Creek transmission line alignment from that approved in 1993.

In transmission line Alternatives B, C-R, D-R, and E-R, the KNF would amend the KFP by reallocating certain areas within a 500-foot corridor of the selected 230-kV transmission line on National Forest System lands as MA 23. A corridor wider than that used in 1993 was used because the final transmission line alignment may be within 250 feet of the centerline analyzed in the EIS and within 250 feet of the approved facility location (centerline) (ARM 17.20.301 (21)). Specifically, the amendment would apply to the following MAs if crossed by the transmission line: MA 10 and 11 if the proposed corridor were within grizzly bear management situation 1 or 2; and MAs 2, 6, 12, 13, and 14. This amendment would apply only to National Forest System lands that currently are not MA 23 disturbed by any transmission line alternative, and would not apply to private or State lands crossed by the transmission line alternatives. Maps showing areas of proposed reallocation are available at the KNF.

3.15.3 Affected Environment

The KNF manages most lands in the land use analysis area (Figure 78), encompassing a total of 13,235 acres in the mine analysis area, and 14,010 acres in the transmission line analysis area. Private land occurs along Libby Creek, Little Cherry Creek, Miller Creek, West Fisher Creek, and Fisher River. Mine facilities associated with the Montanore Project would be developed on patented mining claims and on unpatented mining claims on National Forest System lands under KNF's management. The KNF manages public land for multiple use benefits, including wood products, recreation, range, wildlife, mineral development, and wilderness. Forest industry land is primarily managed for wood products, and private lands are managed to satisfy individual landowner objectives. Plum Creek, Libby Placer Mining Company, or MMC own most of private lands in the land use analysis area. Plum Creek and other property owners own land along the transmission line corridors; Plum Creek also owns the land proposed for the Sedlak Park Substation and loop line; Libby Placer Mining Company and MMC own land near the proposed mine facilities (Figure 78). Private land within the analysis area includes 446 acres owned by MMC, 5,399 acres owned by Plum Creek, and 4,151 acres owned by other private entities.

The National Forest System lands of the Libby Ranger District provide about 6 to 8 million board feet (mmbf) of timber annually. As discussed in section 3.3, *Reasonably Foreseeable Future Actions or Conditions*, the KNF completed an EIS on the Miller-West Fisher Vegetation Management Project in the land use analysis area. Timber harvest activity also occurs on private, forest-industry lands. The amount of timber harvested has declined in the past 10 years. Small-scale timber harvests occur in the range of 2 to 6 mmbf annually on the private lands in the land use analysis area. Plum Creek has harvested several tracts of private, forest-industry lands on lower Miller Creek and along the Fisher River.

One parcel of State land would be crossed by the West Fisher Creek transmission line alignment. The DNRC manages the surface and mineral resources for the benefit of the common schools and six administrative land offices, under the direction of the State Board of Land Commissioners. The DNRC's obligation for management and administration of Trust Land is to obtain the greatest benefit for the beneficiaries. The greatest monetary return must be weighed against the long-term productivity of the land to ensure continued future returns to the trusts. The Northwestern Land Office of the DNRC facilitates local management of the State lands within the land use analysis area. Hunting also occurs on State land (Power Engineers 2005c).

Some mineral activity currently occurs in the land use analysis area, including small placer operations on Libby and Big Cherry creeks, and small lode mining operations along Libby Creek. A number of mineral operators do some form of mine development work along the east face of the Cabinet Mountains each year. The DEQ permitted three small sand and gravel operations within the land use analysis area. One electrical transmission line is located in the land use analysis area. The BPA currently operates the Noxon-Libby 230-kV transmission line near the proposed Sedlak Park Substation. No pipelines 8 inches or greater in diameter occur within 1 mile of the transmission line alternatives. Four Montana Department of Agriculture registered general (commercial) apiaries are located in the land use analysis area. Commercial apiaries are used for honey production and/or pollination. General (commercial) apiary registrations are apiaries placed by permission on someone's property and contain more than five hives.

3.15.3.1 Private Lands

Southern Lincoln County is a rural area with no major population centers. Large-lot residential properties, ranches, and cabins are found along US 2 near Libby Creek Road (NFS road # 231), Bear Creek Road (NFS road # 278), the Fisher River, and Pleasant Valley. The City of Libby is along the Kootenai River about 15 miles north of the land use analysis area. Twenty residences are within 1 mile of the four transmission line alternatives. Most of these properties are within 0.5 mile of US 2 (Figure 79). No platted subdivisions are within 1 mile of the transmission line alternatives. The Libby Adit Site and portions of the Little Cherry Creek Impoundment Site are private lands owned by MMC.

In 2003, Plum Creek sold a conservation easement to the FWP on 142,000 acres in northwest Montana, some of it (3,658 acres) within the land use analysis area (Figure 78). The land covered by the Thompson-Fisher conservation easement offers opportunities for the continuation of forest and resource management, commercial timber harvesting and other commodity use, recreational characteristics, and open space, all of which provide fish and wildlife habitat. The conservation easement was partially funded by the Forest Legacy Program for the purpose of preventing the land from being converted to non-forest uses. One of the stated purposes of the conservation easement is to "preserve and protect in perpetuity the right to practice commercial forest and resource management." The conservation easement was mapped and reviewed during the transmission line screening analysis process (ERO Resources Corp. 2006b).

Plum Creek lands not covered by the conservation easement are currently managed the same as easement lands (*i.e.*, timber harvest and other commodity use, recreation, and wildlife habitat). Because these lands are not subject to the conservation easement, future land uses by Plum Creek or subsequent owners could change to include activities prohibited by the easement (Parker, pers. comm. 2008).

3.15.3.2 Kootenai National Forest Land Management Plan

Land management direction for the KNF is described in the following sections. Management prescriptions are specified for each MA by resource, including recreation, wildlife and fish, timber, soils, water, and air resources, minerals and geology, lands, and facilities. Only National Forest System lands are managed under the KFP.

3.15.3.2.1 Forest-wide Goals, Objectives, and Standards

Goals

Goals provide information on the long-range management intent. The objectives and standards of both the forest as a whole and individual MAs must support the goals. All activities conducted on the KNF must contribute to the realization of the goals (KFP Vol. 1 II-1). The goal for mineral development, discussed under Goal #11 is to "encourage responsible development of mineral resources in a manner that recognizes national and local needs and provides for economically and environmentally sound exploration, extraction, and reclamation." (KFP Vol. 1 II-2). The KFP also establishes a goal of providing a sustained yield of timber volume responsive to market demands and supportive of a stable base of economic growth in the dependent geographic area (KFP Vol. 1 II-1 #1). Goals for wildlife resources include: (1) maintaining and enhancing sufficient habitat to facilitate recovery of threatened and endangered species (KFP Vol. 1 II-1 #6); (2) maintaining diverse age classes of vegetation to support viable populations of existing vertebrate species, including old growth dependent species (KFP Vol. 1 II-1 #7); (3) managing for sufficient snags (dead standing trees) to maintain viable populations of snag-dependent species (KFP Vol. 1 II-1 #8); and (4) maintaining big game and fisheries habitat (KFP Vol. 1 II-2 #12, #13). For water quality, the KFP establishes a goal of meeting or exceeding state water quality standards (KFP Vol. 1 II-1 #19). To achieve this goal, forest-wide objectives for water quality require application of practicable mitigation measures, including those identified in the Soil and Water Conservation Handbook (USDA Forest Service 1988b).

Objectives

Mineral exploration and development may occur on nearly all areas of the KNF; areas withdrawn from future mineral entry include the CMW and developed recreation sites. MMC currently holds mineral rights inside the CMW established before the legislatively mandated withdrawal date. The objective concerning minerals requires consideration of other resources during mineral exploration and development (KFP Vol. 1 II-8).

Objectives for facility corridors, such as a transmission line, are discussed under Corridors in the KFP. The objectives establish corridor exclusion, avoidance, and window areas to assist in corridor siting (KFP Vol. 1 II-11). Criteria for these areas are outlined in Appendix 15, Corridor Criteria, of the KFP. Goals and objectives for cultural resources, recreation, visual resources, air quality, road management, and riparian areas have also been established and are described in the KFP (KFP Vol. 1 II-5, II-6, II-10, II-11). These are described in other sections of this chapter.

Standards

The minerals standard requires the KNF to “recognize the value and importance of the mineral resource in management activities” (KFP Vol. 1 II-27). Road access for mineral development “will be allowed if it is the next logical step in the development of the mineral resource,” subject to the restriction of various laws, such as the Wilderness Act and the ESA. Plans of Operations for mineral development must include “reasonable and justified” requirements designed to minimize environmental impacts (KFP Vol. 1 II-27). Under the minerals standard, the KNF will provide guidance to the mineral industry, where possible, to assist in developing mining plans that minimize environmental damage (KFP Vol. 1 II-27).

3.15.3.2.2 Management Area Goals and Standards

The KFP describes the goals and standards for 24 MAs located on the forest. The MAs within or adjacent to the land use analysis area are described in the following sections (maps of these management areas are available from KNF). The standards are summarized in Table 138. MAs classified as corridor exclusion or corridor avoidance areas are shown on Figure 79. For all MAs discussed in the following sections, the standard for minerals refers to the forest-wide standards described in the above section. In all MAs, soil and water conservation practices are to be implemented for all developmental activities.

Semi-primitive Non-motorized Recreation (MA 2). The goal of MA 2 is to provide the protection and enhancement areas for roadless recreation use and to provide for wildlife management where specific wildlife values are high. In some areas, this MA provides habitat that will contribute to grizzly bear recovery. Some roads are currently open to some form of motorized recreational use, including snowmobiles. Forest-wide standards for mineral development apply. Roads may be justified for mineral activities. This MA is classified as a corridor avoidance area (KFP Vol. 1 III-5).

Table 138. Summary of Relevant Standards in Selected Management Areas on the KNF.

Management Area	Locatable Mineral Development	Powerline Corridors	Lands and Facility Occupancy	Motorized Access	Wildlife	Logging	Visual Quality Objective	Road Development
Semi-primitive non-motorized recreation (MA 2)	Forest-wide standards apply	Avoidance area	Frequently used facilities normally prohibited	Closed, except for limited exceptions	Grizzly habitat	Unsuitable	Retention	Generally prohibited; existing roads may be used for mineral development on a case-by-case basis; new roads permitted when justified by mineral information
Developed recreation sites (MA 6)	Restricted	Avoidance area	Permitted	Restricted	Provide habitat	Unsuitable	Partial retention	Restricted
Existing wilderness (MA 7)	Valid mineral rights will be managed per existing laws and regulations	Avoidance area	Prohibited	Restricted	Provide habitat	Unsuitable	Preservation	Restricted
Big game winter range (MA 10)	Forest-wide standards apply	Avoidance area	Permitted with winter restrictions	Closed during winter	Maintain openings for big game	Unsuitable	See footnotes†‡	Restricted
Big game winter range/timber (MA 11)	Forest-wide standards apply	Avoidance area	Permitted with winter restrictions	Closed during winter	Maintain openings for big game	Suitable	See footnotes†‡	Restricted
Big game summer range (MA 12)	Forest-wide standards apply	Avoidance area	Frequently used facilities normally prohibited	Roads generally closed	Big game and grizzly habitat	Suitable	See footnote†	Restricted
Designated old growth timber (MA 13)	Forest-wide standards apply	Avoidance area	Restricted	Prohibited during summer/fall	Grizzly bear and old growth species habitat	Unsuitable	See footnotes†‡	Restricted

Table 138. Summary of Relevant Standards in Selected Management Areas on the KNF. (cont'd).

Management Area	Locatable Mineral Development	Powerline Corridors	Lands and Facility Occupancy	Motorized Access	Wildlife	Timber Production	Visual Quality Objective	Road Development
Grizzly habitat (MA 14)	Forest-wide standards apply	Avoidance area	Generally prohibited	Allowed, with restrictions	Grizzly habitat	Suitable	See footnote†	Restricted during active grizzly use
Timber production (MA 15)	Forest-wide standards apply	Permitted	Permitted	Allowed	Provide habitat	Suitable	Maximum modification	Allowed
Timber with viewing (MA 16)	Forest-wide standards apply	Permitted	Permitted	Allowed	Provide habitat	Suitable	Modification	Allowed
Viewing with timber (MA 17)	Forest-wide standards apply	Permitted	Permitted	Allowed	Provide habitat	Suitable	Partial retention	Allowed
Revegetation problem areas (MA 18)	Forest-wide standards apply	Permitted	Permitted	Allowed	Provide habitat	Unsuitable	See footnote†	Restricted
Steep lands (MA 19)	Forest-wide standards apply	Permitted	Permitted	Allowed	Provide habitat	Unsuitable	See footnote†	Allowed
Electric Transmission Corridor (MA 23)	Forest-wide standards apply	Permitted	Permitted	Allowed, with possible public access restriction	Grizzly habitat	Unsuitable	Maximum modification	Allowed
Low Productivity Areas (MA 24)	Forest-wide standards apply	Case-by-case basis	Case-by-case basis	Allowed, with restrictions	Grizzly habitat	Unsuitable	See footnote†	Restricted
Mineral Development (MA 31)	Forest-wide standards apply	Case-by-case basis consistent with mineral production facility	Case-by-case basis consistent with mineral production facility	Allowed	Locate facilities, if possible, away from important winter range, calving areas, riparian areas, and meadows	Unsuitable	Maximum modification	Allowed

†Maximum modification in areas of low visual significance, modification in areas of moderate visual significance, and partial retention in areas of high visual significance.
‡Unless infeasible when attempting to meet the goals of the Management Area.
Source: USDA Forest Service 1987.

Developed Recreation Sites (MA 6). MA 6 includes developed campgrounds, picnic areas, boat ramps, and other developed recreation sites. Areas are usually associated with water features such as lakes, reservoirs, and streams. The goal of MA 6 is to provide safe and sanitary developed recreation in a setting that is pleasant and visually attractive. This MA is usually withdrawn from mineral development, and is classified as a corridor avoidance area (KFP Vol. 1 III-18).

Existing Wilderness (MA 7). The goal of MA 7 is to manage in accordance with the Wilderness Act of 1964, to allow natural processes to continue, maintain the opportunity for solitude and primitive recreation, provide habitat contributing to the recovery of the grizzly bear, and provide natural habitat for viable populations of other species of wildlife which have historically occupied the area. This MA is classified as a corridor avoidance area (KFP Vol. 1 III-23).

Big Game Winter Range (MA 10). The goal of MA 10 is to maintain or enhance the habitat effectiveness for winter use by big-game species including elk, moose, sheep, goats, whitetail deer, and mule deer. The goal also is to maintain or enhance visual resources in areas visible from major travel corridors. This MA is classified as a corridor avoidance area (KFP Vol. 1 III-40).

Big Game Winter Range/Timber (MA 11). The goal for MA 11 is to maintain and enhance winter range habitat effectiveness for big game species while also producing a programmed yield of timber and maintaining the scenic resource in areas of high visual significance. The standards concentrate on protection of important wintering areas and providing optimum habitat for elk, mule deer, whitetail deer, moose, sheep, and goats for winter survival. These areas are corridor avoidance areas in grizzly bear habitat. Programmed timber harvest is authorized (KFP Vol. 1 III-45).

Big Game Summer Range/Timber (MA 12). The goal for MA 12 emphasizes maintenance or enhancement of summer and fall big game habitat while producing a programmed yield of timber. The goals and standards focus on providing big game habitat diversity for black bear, grizzly bear, elk, moose, mule deer, and whitetail deer. Timber production will be maintained through cultural treatments and regeneration harvest designed to reduce the frequency of entries. Facilities that require frequent maintenance or occupancy are normally not allowed. This MA is a corridor avoidance area in areas important to grizzly bear use (KFP Vol. 1 III-51).

Designated Old Growth Timber (MA 13). MA 13 provides the special habitat necessary for old growth-dependent wildlife on at least 10 percent of the land area within each major drainage, and in units that represent the major habitat types and tree species of each drainage. The standards emphasize providing diverse, high quality, year-round habitat for old growth-dependent wildlife (usually other than big game) by relying on natural processes of stand aging, decadence and eventual deterioration. This MA is classified as a corridor avoidance area (KFP Vol. 1 III-56).

Grizzly Bear Habitat/Timber (MA 14). MA 14 is designed to maintain or enhance grizzly bear habitat, reduce grizzly/human conflicts, assist in the recovery of the grizzly bear, realize a programmed level of timber production, and provide for the maintenance or enhancement of other wildlife, especially big game. Identified grizzly habitat components will be maintained or enhanced, and key components such as wet meadows and bogs will be mapped and managed as riparian areas. This MA is classified as a corridor avoidance area (KFP Vol. 1 III-60).

Timber Production (MA 15). The goal of MA 15 is to produce timber volumes suitable for harvest by conventional methods while providing for other resource values such as soil, air, water, wildlife, recreation and forage for domestic livestock. This MA has standards and guidelines for providing optimum timber production by ensuring full stocking through natural and artificial regeneration, and maintaining optimal volume growth through stocking control by thinning. Most roads are open for motorized recreation. Transmission line corridors are permitted (KFP Vol. 1 III-66).

Timber with Viewing (MA 16). The goal of MA 16 is to produce timber while providing for a pleasing view. This MA is characterized by productive forest land that has moderate viewing sensitivity. There are no identified habitats for threatened or endangered species. Most roads are open for motorized recreation. Transmission line corridors are permitted (KFP Vol. 1 III-71).

Viewing with Timber (MA 17). The goal of MA 17 is to provide landscapes that are pleasing to the viewer, while producing a level of timber production that is compatible with visual resource protection. Roads are generally located so they are not visible from major travel corridors. Transmission line corridors are permitted (KFP Vol. 1 III-76).

Regeneration Problem Areas (MA 18). MA 18 occurs on areas of slope in excess of 40 percent where timber productivity is moderate to high. This MA is distinguished by the difficulty in establishing coniferous regeneration after timber harvest. The goals of this MA are to maintain the existing coniferous vegetation until techniques and practices are available to ensure that timber can be harvested and the area adequately regenerated within 5 years of harvest, and to maintain viable populations of existing native wildlife species. Because of the sensitivity of MA 18, water quality and soil erosion will be monitored as part of any surface disturbance activity. Transmission line corridors are permitted (KFP Vol. 1 III-81).

Steep Lands (MA 19). MA 19 occurs on steep slopes and breaklands over 60 percent where timber productivity is moderate to high. The soil is usually erodible or the land unstable due to steepness. The goal of MA 19 is to ensure soil stability and water quality by maintaining vegetation in a healthy condition and by minimizing surface disturbance. While many wildlife species use these areas, they are not known to be essential to any species (KFP Vol. 1 III-83).

Electric Transmission Corridor (MA 23). The goal for MA 23 is to provide for the transmission of electricity in a safe and efficient manner. The goal is also to protect the adjacent wilderness character, contribute to the diversity of surrounding wildlife habitat, and provide as much security as possible for the grizzly bear. The VQO is maximum modification (KFP Vol. 1 III-113).

Low Productivity Areas (MA 24). This MA consists of moderate to steep slopes, is usually rocky with thin soils, and often occurs on glacially-scoured ridgetops, walls, or talus slopes. MA 24 is generally located at mid to high elevations and has relatively little productive capacity for many of the surface resources. The goal for MA 24 is to manage primarily for site protection, and for any wildlife resources that may exist (KFP Vol. 1 III-116).

Mineral Development (MA 31). The goal of MA 31 is to provide mineral production workers with safe and healthful working areas that are in concert with the surrounding MAs as much as possible. Additional sites for this MA will be provided as demand and successful mineral discoveries permit. The VQO is maximum modification (KFP amendments).

Riparian Areas. In 1995, the KNF amended the KFP to adopt the INFS (USDA Forest Service 1995) to establish stream, wetland, and landslide-prone area protection zones called RHCAs. These RHCAs are designated along most of the streams in the land use analysis area. Section 3.6, *Aquatic Life and Fisheries* provides more information about the standards and guidelines for managing activities within a RHCA.

3.15.4 Environmental Consequences

3.15.4.1 Alternative 1 – No Mine

The changes in land use associated with a mine would not occur. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150, would remain in effect. The DEQ's approval of revisions to DEQ Operating Permit #00150 (Minor Revisions 06-001 and 06-002) also would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Disturbances on private land at the Libby Adit Site would remain until reclaimed in accordance with existing permits and approvals. Use of National Forest System lands would continue to be managed in accordance with the KFP. Existing land use of private land in the Little Cherry Creek Tailings Impoundment Site and along the Bear Creek Road (NFS road #278) would continue.

3.15.4.2 Alternative 2 – MMC's Proposed Mine

Most of the proposed mine facilities would be on National Forest System lands. The management emphasis of these lands is listed in Table 138. Most of the lands are currently managed for mineral development, wildlife habitat, recreation, and commercial timber production. During the life of the operation, use of the lands within the permit areas would be devoted to mining and associated activities. The operating permit area and the disturbance along the Bear Creek access road (NFS road #278) would total 3,628 acres; about 2,582 acres would be disturbed. Adjacent land use during the operation would be affected to some extent; these impacts are described in other sections on recreation, noise, scenic resources, and wildlife. Disturbance at the Libby Adit Site, Rock Lake Ventilation Adit Site, and portions of the Little Cherry Creek Impoundment Site (286 acres) are private lands owned by MMC (Table 139). LAD Area 2 would be immediately adjacent to private land along Libby Creek (Figure 78). Disturbance associated with the Little Cherry Creek Impoundment Site and LAD Area 2 may result in indirect effects on adjacent private lands. These effects on air quality, aquatic life and fisheries, surface water hydrology, scenery, and sound are discussed in greater detail in sections 3.4.4, 3.6.4, 3.11.4, 3.17.4, and

Table 139. Summary of Land Ownership and Disturbance Areas for each Mine Alternative.

Ownership	Alternative 2 – MMC's Proposed Mine	Alternative 3 – Agency Mitigated Poorman Impoundment Alternative	Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative
National Forest System Land	2,288	1,549	1,639
MMC Owned	286	16	276
Other Private	9	9	9
Total	2,582	1,565	1,924

All units are in acres.

Source: GIS analysis by ERO Resources Corp. using KNF data.

3.20.4. Widening of the Bear Creek Road would affect about 9 acres of private land in three separate parcels between 1 and 3 miles south of the road's intersection with US 2.

MMC would purchase 2,758 acres of private lands to mitigate for habitat losses not offset by KNF's road access changes. In some instances, MMC may purchase a conservation easement with fee title remaining with the private party. The conveyance of title or a conservation easement on private land would restrict future residential and commercial development on 2,758 acres of private lands.

All lands disturbed by the project would be revegetated and, except for the Bear Creek Road and the tailings impoundment facilities, would return to pre-mine uses and productivity over time. The Bear Creek Road from US 2 to the Bear Creek Bridge would not be restored to its narrower pre-mining width. Successful reclamation would result in reforestation of disturbed lands. The goal of reclamation would be to restore lands to productive use. The Little Cherry Creek Tailings Impoundment and the upper part of the Diversion Channel would not support pre-mining timber production. The disturbance associated with the Bear Creek Road widening also would not support pre-mining timber production.

In all alternatives, the KFP would be amended for portions of the mine permit areas that are not currently designated for mineral development (MA 31). A few areas currently designated for mineral development also would be reallocated to other Management Areas. In Alternative 2, 1,816 acres would be reallocated to MA 31 (Table 140). Under MA 31, land management in the mine permit areas would change from the present direction for uses listed in Table 140 to long-term management for mineral development. The MA that would require the most change is currently MA 14, which is managed for grizzly bear habitat. Because the permit area at the Ramsey Plant Site is better defined than in 1993, 25 acres at the site would be reallocated from MA 31 back to MA 2, semi-primitive non-motorized recreation. Similarly, 5 acres at the Little Cherry Creek Impoundment Site would be reallocated back to MA 14, grizzly bear habitat. Maps showing areas of proposed reallocation are available at the KNF.

3.15.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Like Alternative 2, most of the proposed mine facilities would be on National Forest System lands currently managed for wildlife habitat, recreation, mineral development, and commercial timber production. During the life of the operation, use of the lands within the permit areas would be devoted to mining and associated activities. The operating permitted area and the disturbance along the Bear Creek access road (NFS road #278) would total 2,157 acres; about 1,565 acres would be disturbed. Effects of Alternative 3 would be similar to Alternative 2. The Libby Adit Site is private land owned by MMC. The Poorman Impoundment Site would be immediately west of private land along Libby Creek, with the same indirect effects on adjacent private land as Alternative 2. Effects of widening of the Bear Creek Road would be the same as Alternative 2.

Table 140. Acres of National Forest System Land to be Reallocated by Management Area for each Mine Alternative.

Management Area Allocation	Alternative 1 – No Mine (Existing Conditions)	Alternative 2 – MMC's Proposed Mine		Alternative 3 – Agency Mitigated Poorman Impoundment Alternative		Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative	
	(Acres)	With Project (acres)	Change (Acres)	With Project (acres)	Change (Acres)	With Project (acres)	Change (Acres)
MA 2-Semi-primitive non-motorized recreation	2,402	2,219	-183	2,392	-10	2,393	-9
MA 6-Developed recreation sites	86	86	0	86	-<1	86	-<1
MA 7-Existing wilderness	66	66	0	66	0	66	0
MA 11-Big game winter range/timber	1,099	1,099	0	1,099	0	1,099	0
MA 13-Old growth timber†	2,388	2,016	-372	2,129	-259	2,044	-344
MA 14-Grizzly habitat	3,552	2,767	-785	3,166	-386	3,256	-296
MA 15- Timber production	121	121	0	121	0	121	0
MA 16-Timber with viewing	1,858	1,385	-473	1,752	-106	1,385	-473
MA 17-Viewing with timber	329	295	-34	329	0	295	-34
MA 18-Regeneration problem areas	12	12	0	12	0	12	0
MA 19-Steep lands	14	14	0	14	0	14	0
MA 23-Electric transmission corridor	200	180	-20	178	-22	178	-22
MA 31-Mineral development	1,108	2,975	1,867	1,891	783	2,286	1,178
Total	13,235	13,235		13,235		13,235	

Acreage based on the permit areas surrounding the adit sites, plant site, tailings impoundment, and in Alternative 2, LAD Areas.
†The KNF would reallocate 797 acres of old growth in Alternative 3 and 828 acres in Alternative 4 to MA 13 (Table 179). The reallocated stands of old growth have not been identified specifically, and would be before issuance of a ROD.
Source: GIS analysis by ERO Resources Corp. using KNF data.

MMC would acquire or place a conservation easement on 5,387 acres of private land for grizzly bear mitigation in Alternative 3. MMC also would convey land used for isolated wetland mitigation along Little Cherry Creek to the Forest Service. The conveyance of title or a conservation easement on private land would restrict future residential and commercial development on these lands.

All lands disturbed by the project would be revegetated and, except for the Bear Creek Road and the tailings impoundment facilities, would return to pre-mine uses and productivity over time. The Poorman Tailings Impoundment and the disturbance associated with the Bear Creek Road widening would not support pre-mining timber production.

In Alternative 3, the KFP would be amended to reallocate 783 acres to MA 31 (Table 140). Under MA 31, land management in the mine permit areas would change from the present direction for uses listed in Table 140 to long-term management for mineral development. The MAs that would require the most change is MA 13 (259 acres of old growth timber) and MA 14 (386 acres of grizzly bear habitat). Because the permit area would not include Ramsey Plant Site, 150 acres at the Ramsey Plant Site would be reallocated back to MA 2, semi-primitive non-motorized recreation. Similarly, 466 acres at the Little Cherry Creek drainage (outside of the permit area for the tailings impoundment) would be reallocated back to MA 14, grizzly bear habitat. Maps showing areas of proposed reallocation are available at the KNF.

3.15.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Like the other alternatives, most of the proposed mine facilities in Alternative 4 would be on National Forest System lands currently managed for grizzly bear habitat. Management emphasis of the permit area of other facilities is mineral development, recreation, and commercial timber production. During the life of the operation, use of the lands within the permit areas would be devoted to mining and associated activities. The permitted area and the disturbance along the Bear Creek access road (NFS road #278) would total 2,979 acres; about 1,924 acres would be disturbed. Effects of Alternative 4 would be similar to Alternative 2. Land use of MMC's private land at the Libby Adit Site, Rock Lake Ventilation Adit Site, and the Little Cherry Creek Impoundment Site would be the same as Alternative 2. Indirect effects of the Little Cherry Creek Impoundment Site on adjacent private land, and the effects of widening of the Bear Creek Road would be the same as Alternative 2.

MMC would acquire or place a conservation easement on 6,151 acres of private land for grizzly bear mitigation in Alternative 4. The conveyance of isolated wetland mitigation lands would be the same as Alternative 3. The conveyance of title or a conservation easement on private land would restrict future residential and commercial development on these lands.

All lands disturbed by the project would be revegetated and, except for the Bear Creek Road and the tailings impoundment facilities, would return to pre-mine uses and productivity over time. The Little Cherry Creek Tailings Impoundment, upper part of the Diversion Channel, and the disturbance associated with the Bear Creek Road widening would not support pre-mining timber production.

The KFP would be amended to change the management allocation to mineral development (MA 31) on 1,178 acres from the present direction for uses listed in Table 140. About 344 acres of the land to be reallocated is currently MA 13 (old growth timber) and 296 acres are MA 14 (grizzly bear habitat). The permit area would not include Ramsey Plant Site, and 150 acres at the Ramsey Plant Site would be reallocated from MA 31 back to MA 2, semi-primitive non-motorized recreation. Similarly, 228 acres at the Little Cherry Creek Impoundment Site outside of the permit area for the tailings impoundment would be reallocated back to MA 14, grizzly bear habitat. Maps showing areas of proposed reallocation are available at the KNF.

3.15.4.5 Alternative A – No Transmission Line

In Alternative A, the transmission line, Sedlak Park Substation, and the loop line for the Montanore Project would not be built. No changes in land use in Alternative A would occur. Use of National Forest System lands would continue to be managed in accordance with the KFP. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Existing land use of State land along West Fisher Creek, Plum Creek lands, and private land along US 2 and at scattered parcels in the Miller Creek, West Fisher Creek and Standard Creek drainages would continue.

3.15.4.6 Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

3.15.4.6.1 Direct Effects

In the North Miller Creek Alternative, the alignment would cross Plum Creek land in the Fisher River valley and in three sections immediately west of the Fisher River (Figure 78). These segments would parallel existing road corridors (roads on Plum Creek lands, US 2 and NFS road #385). Alternatives B through E-R would use or parallel existing road corridors, including open, gated, barriered, or impassable roads. The North Miller Creek Alternative would have 5.1 miles of centerline within 100 feet of an existing road (Table 141).

Table 141. Use of Existing Road Corridors.

Alternative	Miles of Centerline within 100 Feet of Existing Road Corridors
Alternative B – North Miller Creek Alternative	5.1
Alternative C-R – Modified North Miller Creek	3.8
Alternative D-R – Miller Creek	3.6
Alternative E-R – West Fisher Creek	5.9

Source: GIS analysis by ERO Resources Corp. using KNF data.

All transmission line alternatives would include the Sedlak Park Substation and loop line (steel monopoles would be used). The Sedlak Park Substation and loop line would affect 4.4 acres of Plum Creek land, all of which are covered by the conservation easement. About 7.2 miles of Plum Creek land would be crossed, 5.4 miles of which are covered by the conservation easement with FWP. Two sections of Plum Creek land west of the Fisher River not covered by the conservation easement with FWP would be crossed. Clearing of up to 129 acres of Plum Creek land, which is compatible with Plum Creek's land management, would be needed for the transmission line (Table 142). About 10 acres of additional clearing would be needed for access road construction on private land (Table 143). Following construction, the transmission line could restrict cable logging in areas adjacent to the line. Plum Creek land is managed primarily for timber production; some dispersed recreation also occurs on Plum Creek land. This alternative would cross less than 0.1 mile of other private land near the Fisher River.

Table 142. Summary of Land Ownership within Clearing Areas for each Transmission Line Alternative.

Ownership	Alternative B – North Miller Creek		Alternative C-R – Modified North Miller Creek		Alternative D-R – Miller Creek		Alternative E-R – West Fisher Creek	
	(ac.)†	(mi.)	(ac.)	(mi.)	(ac.)	(mi.)	(ac.)	(mi.)
National Forest System Land	168	9.3	206	8.5	220	9.1	200	8.3
State of Montana	0	0.0	6	0.2	6	0.2	25	1.1
Plum Creek (with conservation easement)	97	5.4	86	3.6	86	3.6	89	3.7
Other Plum Creek	32	1.8	19	0.8	19	0.8	49	2.0
Other Private	1	<0.1	0	0.0	0	0.0	0	0.0
Total	297	16.4	317	13.1	331	13.7	363	15.1

All values are in acres.
†Acreage is based on a 150-foot clearing width for monopoles (Alternative B) and 200-foot width for H-frame structures (other alternatives except for a short segment of the West Fisher Creek Alternative that has monopoles). Actual acreage cleared would be less than listed and would depend on tree height, slope, and line clearance above the ground.
Totals may vary slightly due to rounding.
Source: GIS analysis by ERO Resources Corp. using KNF data.

Table 143. Estimated Road Construction or Reconstruction in Each Transmission Line Alternative.

MA Direction on Road Development†	Alternative B – North Miller Creek		Alternative C-R – Modified North Miller Creek		Alternative D-R – Miller Creek		Alternative E-R – West Fisher Creek	
	(ac.)	(mi.)	(ac.)	(mi.)	(ac.)	(mi.)	(ac.)	(mi.)
National Forest System Lands - Road Construction Allowed (MAs 15, 16, 23, 31)	5.8	1.9	1.4	0.4	5.2	1.7	1.4	0.5
National Forest System Lands - Road Construction Restricted (MAs 2, 6, 10, 11, 12, 13, 14, 18, 19, 24)	14.9	5.0	3.0	1.0	5.3	1.7	4.9	1.6
State Lands	0.0	0.0	0.5	0.2	0.5	0.2	0.4	0.2
Private Lands	10.0	3.3	4.5	1.5	4.5	1.5	5.0	1.6
Total	30.7	10.2	9.4	3.1	15.5	5.1	11.7	3.9

New roads and roads with extensive requirements for upgrading are assumed to be 25 feet wide. Values are rounded to the nearest 0.1 acre and mile, and conversion between the two may vary due to rounding.
†See Table 138. for MA descriptions. Values reflect MA status after KFP amendment.
Source: GIS analysis by ERO Resources Corp. using KNF data.

Table 144. Acres of KNF land to be Reallocated by Management Area for each Transmission Line Alternative.

Management Area Emphasis	Timber Harvest Suitability	Alternative A	Alternative B – North Miller Creek		Alternative C-R – Modified North Miller Creek		Alternative D-R – Miller Creek		Alternative E-R – West Fisher Creek

Total		14,010	14,010		14,010		14,010		14,010	

Acreage calculated on the basis of a 500-foot corridor along transmission line centerline to allow for flexibility during final design of the line.
†The KNF would reallocate 36 acres of old growth in Alternative C-R, 12 acres in Alternative D-R, and 3 acres in Alternative E-R (Table 180). The reallocated stands of old growth have not been identified specifically, and would be before issuance of a ROD.
Source: GIS analysis by ERO Resources Corp. using KNF data.

MMC would purchase 68 acres of private lands to mitigate for habitat losses not offset by KNF's road access changes. In some instances, MMC may purchase a conservation easement with fee title remaining with the private party. The conveyance of title or a conservation easement on private land would restrict future residential and commercial development on 68 acres of private lands.

Alternative B would remove 104 acres of timber production on lands covered by FWP's conservation easement. MMC did not propose to mitigate for this loss of timber production.

The remaining 9.3 miles of North Miller Creek Alternative would be on National Forest System lands managed by the KNF. Because the alternative uses the same alignment that was approved in 1993, about a third of the alignment (3.1 miles) would cross lands currently managed for electric transmission corridors. The line would cross 3.0 miles of land that the KFP has identified as corridor avoidance areas (Figure 79). Of the 3.0 miles of corridor avoidance areas, most (2.5 miles) are currently managed for big game winter range (MA 11), with the remaining 0.5 mile is split between four different MAs. Fourteen residences are within 0.5 mile of this alignment (Figure 79), 11 of which are greater than 450 feet from the centerline of the right-of-way and the remaining three are within 450 feet. About 1,760 feet of this alternative would pass through the Libby Creek Recreational Gold Panning Area.

All transmission line alternatives would require construction of between 3 and 10 miles of new access roads or extensive upgrading of existing access roads. About 1.9 miles of roads would be constructed in areas where road construction is allowed under the KFP, and 5 miles of roads would be in areas where road construction is restricted in some manner (Table 143). For example, MA 11 indicates roads will normally be closed during big game winter use (December 1 to April 30). MMC proposes to restrict motorized activity associated with transmission line construction from April 1 to June 15 within bear habitat in the Miller Creek and Midas Creek drainages. MMC also would restrict transmission line construction during the winter in big-game winter range areas (MA 11).

3.15.4.6.2 Forest Plan Amendment

The North Miller Creek Alternative would require a KFP amendment on lands that would be reallocated, as shown in Table 144. MA 11 (big game winter range/timber) would be reduced by 145 acres and MA 23, electric transmission corridor, would increase by 141 acres. Maps showing areas of proposed reallocation are available at the KNF.

3.15.4.7 Alternative C-R – Modified North Miller Creek Transmission Line Alternative

3.15.4.7.1 Direct Effects

The Modified North Miller Creek Alternative would affect Plum Creek land in the Fisher River valley and in three sections immediately west of the Fisher River similar to the North Miller Creek Alternative (Figure 78). About 4.3 miles of Plum Creek land would be crossed, all of which are covered by the conservation easement with FWP. The Sedlak Park Substation and loop line would affect 4.4 acres of Plum Creek land, all of which are covered by the conservation easement. No other private land would be affected (Table 142). This alternative would use H-frame structures, which have a wider clearing width than the monopoles proposed in Alternative B; up to 105 acres of Plum Creek land and 6 acres of State land would require clearing for the transmission line. Some additional clearing would be needed for access road construction (Table

143). Alternative C-R would have 3.8 miles of centerline within an existing road corridor (Table 141).

The remaining 8.5 miles of the Modified North Miller Creek Alternative would be on National Forest System lands. All four residences within 0.5 mile of this alignment are more than 450 feet from the centerline. Like Alternative B, 1,750 feet of Alternative C-R would pass through the Libby Creek Recreational Gold Panning Area in the same location.

A minimum of 26 structures (about 4.2 miles of line) would be set using a helicopter, minimizing new access road construction or extensive upgrading of closed roads). Additional structures may be set using a helicopter at the contractor's discretion. About 0.4 mile of roads would be constructed in areas where road construction is allowed currently under the KFP, and 1 mile of roads would be in areas where road construction is restricted currently in some manner (Table 143).

Alternative C-R would physically disturb 13 acres of grizzly bear habitat and remove 91 acres of timber production on lands covered by FWP's conservation easement. As mitigation, MMC would acquire or place a conservation easement on 26 acres of private land for grizzly bear mitigation in Alternative C-R. In addition, MMC would convey title or a conservation easement to FWP to up to 91 acres of private land. The acquisition of or placement of a conservation easement on private land would restrict future residential and commercial development on these lands.

3.15.4.7.2 Forest Plan Amendment

The Modified North Miller Creek Alternative would require a KFP amendment on lands that would be reallocated to MA 23. The net change to each management area is shown in Table 144. Most of the lands that would be reallocated would be MA 11, big game winter range/timber (137 acres) and MA 2, semi-primitive non-motorized recreation (126 acres). Maps showing areas of proposed reallocation are available at the KNF.

3.15.4.8 Alternative D-R – Miller Creek Transmission Line Alternative

3.15.4.8.1 Direct Effects

The Miller Creek Alternative would have essentially the same effect on Plum Creek land in the Fisher River valley and in three sections immediately west of the Fisher River as the Modified North Miller Creek Alternative. This alternative also would use H-frame structures; up to 105 acres of Plum Creek and 6 acres of State land would require clearing for the transmission line. Some additional clearing would be needed for access road construction. It would make least use of existing road corridors, with 3.6 miles of centerline within 100 feet of existing roads (Table 141).

The remaining 9.1 miles of the Miller Creek Alternative would be on National Forest System lands. All six residences within 0.5 mile of this alignment are more than 450 feet from the centerline. About 2,120 feet of the alignment would pass through the Libby Creek Recreational Gold Panning Area.

A minimum of 16 structures (about 2.4 miles of line) would be set using a helicopter; additional structures may be set using a helicopter at the contractor's discretion. About 1.7 mile of roads would be constructed in areas where road construction is allowed currently under the KFP, and 1.7 mile of roads would be in areas where road construction is restricted currently in some manner (Table 143).

MMC would acquire or place a conservation easement on 40 acres of private land for grizzly bear mitigation in Alternative D-R. The acquisition of or placement of a conservation easement on private land would restrict future residential and commercial development on these lands. The mitigation for loss of 91 acres of timber production on lands covered by FWP's conservation easement would be the same as Alternative C-R.

3.15.4.8.2 Forest Plan Amendment

The Miller Creek Alternative would require a KFP amendment on lands that would be reallocated as shown in Table 144. MA 12, which currently is managed for big game summer range would decrease by 114 acres, and MA 2 which is managed for semi-primitive non-motorized recreation would increase by 126 acres. Like Alternative C-R, most of the land that would be reallocated from MA 23 to MA 2 is in the Ramsey Creek drainage. Maps showing areas of proposed reallocation are available at the KNF.

3.15.4.9 Alternative E-R – West Fisher Creek Transmission Line Alternative

3.15.4.9.1 Direct Effects

The West Fisher Creek Alternative would cross 5.7 miles of Plum Creek lands, 3.7 miles of which is covered under the conservation easement. This alternative would use H-frame structures, except in the section of State land west of the Fisher River (Figure 78). Up to 138 acres of Plum Creek land would require clearing for the transmission line. Some additional clearing would be needed for access road construction. The Sedlak Park Substation and loop line would affect 4.4 acres of Plum Creek land, all of which are covered by the conservation easement. No other private land would be affected. Up to 25 acres of State land would require clearing for construction of the transmission line.

The remaining 8.3 miles of the West Fisher Creek Alternative would be on National Forest System lands. All six residences within 0.5 mile of this alignment are more than 450 feet from the centerline. About 2,120 feet of the alignment would pass through the Libby Creek Recreational Gold Panning Area. Alternative E-R would make the best use of corridors, with 5.9 miles of the centerline within 100 feet of existing roads (Table 141).

A minimum of 31 structures (about 4.5 miles of line) would be set using a helicopter; additional structures may be set using a helicopter at the contractor's discretion. About 0.5 mile of roads would be required in areas where road construction is allowed currently under the KFP, and 1.6 miles of roads in areas where road construction is not currently allowed (Table 143).

Alternative C-R would physically disturb 15 acres of grizzly bear habitat and remove 94 acres of timber production on lands covered by FWP's conservation easement. As mitigation, MMC would acquire or place a conservation easement on 30 acres of private land for grizzly bear mitigation in Alternative E-R. In addition, MMC would convey title or a conservation easement to FWP to up to 94 acres. The acquisition of or placement of a conservation easement on private land would restrict future residential and commercial development on these lands.

3.15.4.9.2 Forest Plan Amendment

The West Fisher Creek Alternative would require an amendment on lands that would be reallocated as shown in Table 144. Most of the lands that would be reallocated would be MA 11 (big game winter range/timber), which would decrease by 212 acres. MA 23 electric transmission corridor would increase by 159 acres, and MA 2 semi-primitive non-motorized recreation would increase by 126 acres. Maps showing areas of proposed reallocation are available at the KNF.

3.15.4.10 Cumulative Effects

Past actions, such as past mining and road construction, have altered the existing land use. Areas disturbed by past mining and road construction do not provide for timber production or wildlife habitat. Past KFP amendments have changed the MA designations of National Forest System lands. In 1987 when the KFP was issued, the KNF had 1,690 acres allocated to MA 23; MA 31 was not established. Since 1987, the KFP has been amended to allocate 3,473 acres to MA 23 and 1,245 acres to MA 31. In the land use cumulative effects analysis area, previous amendments have allocated 233 acres to MA 23 and 1,108 acres to MA 31. The Rock Creek Project and the Montanore Project would cumulatively increase the amount of National Forest System lands on the KNF managed for transmission line corridors and mineral development.

3.15.4.11 Regulatory/Forest Plan Consistency

Following the amendments to the KFP described in this section and in section 2.12*, Forest Plan Amendment*, the mine and transmission line alternatives would comply with the management area designations of the KFP. Other sections of Chapter 3 discuss compliance with the KFP. If the selected transmission line were approved by the FWP, it would comply with the FWP-Plum Creek conservation easement.

3.15.4.12 Irreversible and Irretrievable Commitments

The tailings impoundment area, about 600 acres in each mine alternative, would be managed for mineral development following operations, and would no longer be managed as suitable for timber production. The area covered by asphalt and gravel by widening the Bear Creek Road would not be returned to pre-mine uses. Timber would be harvested sooner in areas cleared for project facilities. Continued tree clearing along the transmission line would reduce timber production during the life of the project. These resources would be irretrievably affected. Any indirect development associated with the project, such as new permanent residential or commercial development in or around Libby, would likely be permanent.

3.15.4.13 Short-term Uses and Long-term Productivity

In the short term, mine operations would dominate land use on about 2,700 to 3,700 acres, depending on the alternative. Similarly, timber production on 300 to 350 acres, depending on the transmission line alignment, would be eliminated along the transmission line clearing width and access roads. Actual clearing width and lost timber production would be slightly less, and would depend on tree height, slope, and line clearance above the ground. After operations ceased, land uses in most areas affected by the mine, Sedlak Park Substation and loop line, and transmission line would return to pre-mine uses. In addition, 3,000 to 3,800 acres of private land, depending on the alternative, would be acquired and legally dedicated to long-term grizzly bear habitat mitigation.

3.15.4.14 Unavoidable Adverse Environmental Effects

During mine and transmission line construction and operations, all action alternatives would unavoidably alter land use in the land use analysis area.

3.16 Recreation

3.16.1 Regulatory Framework

3.16.1.1 Kootenai Forest Plan

The Forest-wide management direction objectives for recreation outlined in the KFP allows for the maintenance and expansion of trails and developed recreation opportunities (such as campgrounds, picnic areas, and boat launches) as needed to prevent resource damage or to accommodate increased demand, and the expansion of groomed cross-country ski trails and snowmobile trails. The Forest Travel Planning process is used to review, evaluate, and implement the goals and standards of various MAs, with regard to roads, trails, and motorized vehicle use. All recreation activities and management will be based on Recreation Opportunity Spectrum (ROS) inventory (USDA Forest Service 1987a). Management emphasis for individual MAs is described in in Table 138. Executive Order 12962 mandates disclosure of effects on recreational fishing as part of a nationwide effort to conserve, restore, and enhance aquatic systems and provide for increased recreational fishing opportunities.

3.16.1.2 State and Local Plans

Outdoor recreation is an important part of the lifestyle and economy throughout Montana. Recreation survey data presented in the Montana Statewide Comprehensive Outdoor Recreation Plan (SCORP) cited fishing, hunting, and backpacking to be among the top five outdoor recreation activity for Montana residents. Over the next 35 years, SCORP projected increases in developed and undeveloped skiing, challenge activities like mountain climbing, rock climbing, and motorized water activities. Activities that will see large decreases in per capita participation include visiting primitive areas, hunting, and fishing (FWP 2014a).

The FWP manages wildlife populations and establishes limits on fishing and hunting activities statewide including on National Forest System lands. The FWP has several general statewide goals that relate to recreational use in the analysis area (FWP 2009). The FWP's goals are to provide quality opportunities for public appreciation and enjoyment of fish, wildlife, and parks resources, and maintain and enhance the health of Montana's natural environment and the vitality of its fish, wildlife, cultural, and historic resources through the 21st century. The FWP's goals are not enforceable standards. Lincoln County does not have a comprehensive recreation plan.

One 640-acre parcel of State land would be crossed by the West Fisher Creek transmission line alignment. Another parcel of State land is crossed by the Libby Creek Road, which would be used for access during the Evaluation and Construction Phases. The DNRC manages the surface and mineral resources for the benefit of the common schools and six administrative land offices, under the direction of the State Board of Land Commissioners. Hunting also occurs on State land (Power Engineers 2005c).

3.16.2 Analysis Area and Methods

The analysis area includes the area west of US 2, primarily east of the Cabinet Mountains ridge line (except for a ventilation adit located near Rock Lake on the west side of the ridge line), south from the Bear Creek Road corridor and north from NFS road #231. The four transmission line alternative alignment corridors also are included in the analysis area.

A land use inventory of the analysis area, which refined and updated existing recreation-related data, was used for the evaluation of recreation effects (Power Engineers 2005c). One of the components contained in the land use inventory included parks, recreation, and preservation areas. The analysis of recreational impacts was based on the number of roads and trails proposed for closure and the effect these closures would have on recreational access in the area. In addition, secondary effects associated with diminished recreation quality on lands adjacent to mining activities were evaluated.

The analysis of potential changes in ROS classes was based on ROS delineation procedures developed by the Forest Service (USDA Forest Service 2003c). Based on the ROS delineation procedures, the analysis area for the ROS analysis included a 0.5-mile buffer around any road to be used by the project; any new road; and any road proposed for access changes. For roads near the CMW, the buffer was extended 3 miles into the CMW. The analysis only considered National Forest System lands in the analysis area. Anticipated changes to ROS classes along existing and proposed road corridors, adjacent to proposed mine facilities, and along proposed transmission line corridors were mapped and quantified. The analysis considered changes during two mine phases: during construction when the maximum effect of motorized road use would occur and when all of the access changes would have been implemented; and during post-closure when all motorized activity associated with the project would cease.

Changes to ROS classes were evaluated during the summer, when the maximum effect of motorized road use would occur. MMC's and the agencies' proposed access changes would reduce winter motorized activities in some drainages (see Table 28 and Table 29 in Chapter 2). The effects on winter-time ROS would not be significant. Consequently, the disclosure requirements of 40 CFR 1502.22 are not applicable. The anticipated changes in ROS classes are described in this section. Maps showing existing and anticipated ROS classes are available in the project record.

3.16.3 Affected Environment

3.16.3.1 Recreational Opportunities and Uses

Northwest Montana is known for its lakes, rivers, and mountains that provide a variety of recreational opportunities. National Forest System lands make up a large percentage of the Lincoln County land base and offer public access for a variety of motorized and non-motorized recreational activities including: hunting for big game and upland game birds, fishing, hiking, wildlife observation, photography, backpacking, horseback riding, snowmobiling, cross-country skiing, mountain biking, picnicking, sightseeing, off highway vehicle (OHV) use, rock hounding, and camping. Recreational use in the analysis area occurs largely within the 350,000-acre Libby Ranger District. Recreational use of the Libby Ranger District is highest in the summer with camping, hiking, and fishing on the weekends being the major activities. These activities in the analysis area are concentrated at Howard Lake and along popular hiking trails. Recreation activities continue to take place during fall, although use declines. Fall use of the analysis area is mainly dispersed hunting and berry picking.

In the last two decades, the number and types of users have increased in the analysis area, partly as a result of growth in the Flathead Valley and Missoula (Kocis *et al.* 2003). The analysis area provides different types of user experiences; the CMW and the small drainages provide users with a more solitary experience compared to the more structured user experience at Howard Lake or the Libby Creek Recreational Gold Panning Area. The KNF has management responsibility for recreational uses of these lands.

KNF uses the ROS inventory as a tool for defining classes of outdoor recreation opportunity environments, making management decisions, and as a way to communicate recreation priorities with the public (USDA Forest Service 1982). ROS classifies recreational opportunities into six categories: Primitive, Semi-Primitive Non-Motorized, Semi-Primitive Motorized, Roaded Natural, Roaded Modified, and Rural (Table 145) (USDA Forest Service 1990).

Based on an updated ROS mapping protocol (USDA Forest Service 2003c), current ROS classes for the Poorman Creek and Ramsey Creek drainages are Semi-Primitive Motorized, while the Little Cherry Creek drainage and most of the Libby Creek drainage are classified as Roaded Natural and Semi-Primitive Motorized. In the transmission line corridor areas, current ROS classes for the West Fisher Creek, Miller Creek and Midas Creek drainages Roaded Natural, with areas of Semi-Primitive Motorized and Semi-Primitive Non-Motorized in areas between the drainages. All of the CMW in the analysis area was mapped as Semi-Primitive Non-Motorized because of roads extending within 3 miles of the CMW boundary.

Table 145. Description of ROS Classes.

ROS Class	Description
Primitive	Characterized by essentially unmodified natural environment of fairly large size. Interaction between users is fairly low and evidence of other users is minimal. Motorized use is not permitted.
Semi-Primitive Non-Motorized	Characterized by predominantly natural or natural-appearing environment of moderate to large size. Interaction between users is low, but there is often evidence of other users. Motorized use is not permitted.
Semi-Primitive Motorized	Characterized by predominantly natural or natural-appearing environment of moderate to large size. Concentration of users is low, but there is often evidence of other users. Motorized use is permitted.
Roaded Natural	Characterized by predominantly natural appearing environment with moderate evidence of human sights/sounds. Interaction between users is may be low to moderate, with evidence of other users prevalent. Conventional motorized use is provided for in the construction and design of facilities.
Roaded Modified	Characterized by modified natural environment with moderate to high evidence of human sights/sounds. Interaction between users is moderate to high, with evidence of other users prevalent. Conventional motorized use is provided for in the construction and design of facilities.
Rural	Characterized by substantially modified natural environment. Resource modification and utilization practices are primarily to enhance specific recreation activities and to maintain vegetation cover and soil. Sights and sounds of man are readily evident, and the interaction between users is often moderate to high. Facilities for intensified motorized use and parking are available.

Source: KFP, USDA Forest Service 1987.

3.16.3.1.1 Hunting

In Montana, 19 percent of residents hunt, the highest level of participation in the nation (FWP 2007). Every fall, hunters frequent the hunting districts close to Libby. The FWP conducts an annual statewide harvest survey to determine hunter activity throughout the state. Data for hunter activity in the analysis area are summarized in Table 146. The Libby Ranger District has 14 permitted outfitters with five operating in the south end of the district.

Table 146. Analysis Area Hunter Activity by Hunting District.

Hunting District	Location	Species	Year	Hunters	Hunter Days
103	East of US 2	Elk	2011	1,990	16,409
104	West of US 2	Elk	2011	1,345	11,658
100	West of US 2 and East of Montana 58	Goat	2011	6	63
105	West of US 2	Moose	2011	20	272
106	East of US 2	Moose	2011	12	147
123	West of US 2	Sheep	2011	4	56
103	East of US 2	White-tailed and Mule Deer	2011	2,852	20,163
104	West of US 2	White-tailed and Mule Deer	2011	1,988	15,186

Note: The analysis area generally includes only small portions of the much larger Hunting Districts. Hunter days are defined as the number of days or partial days spent hunting by active hunters.
Source: FWP 2012.

Hunting opportunities also are available on private lands as a result of FWP actions through the block management program and conservation easements. The block management program is a cooperative effort between FWP, landowners, and land management agencies to provide free public hunting access to private and isolated public land. Other lands with conservation easements generally offer some level of public hunting access. Hunting in the analysis area occurs on Plum Creek lands covered by a conservation easement, other private lands and also on state school trust land. Hunting on private land is subject to landowner discretion.

3.16.3.1.2 Fishing

Fishing opportunities within the analysis area occur primarily in easily accessible streams and rivers and at Howard Lake. Other lakes in the CMW, including Leigh Lake, Rock Lake, and Geiger Lake, provide additional fishing opportunities. Fishing is a relatively minor activity in Libby Creek, Poorman Creek, Howard Creek and West Fisher Creek. Most fishing in the analysis area occurs on the Fisher River and Howard Lake. For example, total angler days between 2003 and 2009 averaged 3,685 days on Fisher River, 990 days on Howard Lake, and 385 days on Libby Creek (FWP 2012). The proportion of angler days on the Fisher River and Libby Creek that occurs in the analysis are is unknown. The FWP does not track fishing use of Little Cherry Creek, Standard Creek, and Miller Creek because they provide a very small portion of the recreational fishing opportunity.

3.16.3.1.3 Scenic Driving

Scenic driving occurs along the forest roads within the analysis area. The most heavily used roads are the Libby Creek Road (NFS road #231), the Bear Creek Road (NFS road #278), and US 2. Less traveled roads used for scenic driving connect with these primary roads.

3.16.3.1.4 Camping and Picnicking

Howard Lake Campground is the only fee campground within the analysis area. This campground offers swimming, fishing, hiking, boating, a water well, RV sites, and toilets. A maintained trail provides access to dispersed camping on one side of the lake. Easy access to Libby Creek and Libby Lakes trailhead facilitates other recreational opportunities in the area. Average annual use by campers paying the fee for Howard Lake Campground during the 2010 and 2011 seasons was 240 campsites (595 campers) (KNF 2011). Recreationists engaged in day use activities dominate Howard Lake Campground. Recreation visits to Howard Lake are about 3,000 annually in 2004 (Power Engineers 2005c).

Camping at dispersed sites is widely scattered throughout the analysis area. Dispersed camping is generally associated with roads and occurs primarily during the summer and fall months.

3.16.3.1.5 Forest Product Gathering

Firewood gathering, Christmas tree cutting, and huckleberry and mushroom picking occur in the analysis area. Firewood is collected primarily in the spring and fall, but because of the large number of wood-burning stoves in the area, firewood collection is constant. The Forest Service considers huckleberry picking to be an important recreational use of the area, although no information is available concerning the number of individuals who visit the area for this purpose, or the economic values that may result (Jeresek, pers. comm. 2006). Huckleberry season (late summer through early fall) brings many people to the area to take part in the berry harvest. The Forest Service estimates that about 80 percent of the pickers are local residents (Jeresek, pers. comm. 2006).

3.16.3.1.6 Gold Panning

The Libby Creek Recreational Gold Panning Area offers the general public the opportunity to pan for gold in a historical area of placer mining. The area has no developed parking lots or camping facilities. Camping at the area is primitive with dispersed sites.

3.16.3.1.7 Winter Activities

Winter activities include ice fishing, cross-country skiing, and snowmobiling. Winter activities in the analysis area are the most common near Bear Creek and Poorman Creek, which provide good areas for skiing and snowmobiling. Bear Creek Road is plowed all winter by Lincoln County to about 1 mile north of Bear Creek, providing skiing and snowmobiling access to Bear Creek and Poorman Creek areas. Libby Creek Road is currently plowed by Lincoln County to Crazyman Road (NFS road #6209), about 1 mile south of US 2. Some winter activities occur on the unplowed portion of Libby Creek Road. Ice fishing occurs on Howard Lake.

3.16.3.1.8 Trails

Several National Forest System trails access the CMW within the east side of the analysis area (Bear Creek south to West Fisher Creek) (Figure 80). These trails are: Trail 119 Libby Creek, Trail 820 Ramsey Creek, Trail 129 Poorman Creek, Trail 821 Cable Creek, Trail 116 Standard Creek, and Trail 117 Great Northern Mountain. Other trails near the transmission line alternatives include Trail 716 Libby Divide, Trail 118 Miller Creek, Trail 6S Divide 6 Trail, and Trail 859 Kenelty Caves Trail. Some of the National Forest System trails are on roads that are closed to motorized use (Power Engineers 2005c). Other trails within or in proximity to the analysis area are shown in Figure 80.

The Leigh Lake trailhead is the highest used trailhead in the analysis area. The trail is accessible from May 1 to September 30. Between 2001 and 2003, the average number of annual visitors at Leigh Lake was 2,827 and the average number of visitor days (equivalent to one person using the resource for 12 hours) was 3,485 (Power Engineers 2005c). Data was not available for other trails. These trails are generally lightly used, with most of the activity occurring in the summer and fall.

Seasonal use data for managed trailheads and unmanaged trailheads indicate a gradual increase in wilderness use since 1988. Seasonal use data reflect high use during the summer (about 85 percent of total), moderate use during the fall (about 10 percent), and light use during the winter (about 5 percent) (MMI 2005a). The Forest Service estimates total annual visitation to the entire wilderness to be 12,100 (USDA Forest Service 2009)

3.16.4 Environmental Consequences

The road closures described below would restrict both summer and winter recreation access for a variety of recreational uses, including hiking, hunting, fishing, OHV use, snowmobiling, cross-country skiing, berry picking, dispersed camping, and other uses in the affected areas. Secondary effects on recreation activities on lands adjacent to mine facilities would occur from mine- and construction-related noise and disturbance.

3.16.4.1 Alternative 1 – No Mine

Alternative 1 would have no impact upon recreation in the analysis area. Access to roads and trails would continue as in the past. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150, would remain in effect. The DEQ's approval of revisions to DEQ Operating Permit #00150 (Minor Revisions 06-001 and 06-002) also would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Visitors to the area may experience increased noise levels from activities at the Libby Adit Site. These effects would be temporary and there would be no long-term effects on visitors' recreational experiences if no mine were constructed.

3.16.4.2 Alternative 2 – MMC's Proposed Mine

3.16.4.2.1 Short-term Effects During Construction, Operations, and Closure Phases

In general, recreational use and access to the analysis area would continue, although the configuration of some access roads would change slightly and the overall character of recreation opportunities within or adjacent to mine facilities would change substantially. Short-term effects during mine construction, operations, and reclamation would include restricted public access, increased noise, and increased night lighting within and adjacent to the mine facility areas. Public motorized and non-motorized access would be restricted to mine and agency personnel in all permit areas. These effects would reduce the amount of area available for hunting and other dispersed recreation activities. The combination of mine development and improved recreational access may displace some dispersed recreation activities (such as hunting, hiking, and dispersed camping) within the analysis area to other portions of the KNF, since individuals who are currently accustomed to these areas may use other areas of the forest with fewer visitors and developed facilities. The overall effect on recreation use and opportunity in the KNF would be negligible.

The proposed mine and associated facilities in Alternative 2 would reduce public recreational access due to road closures. Public motorized and non-motorized access would be restricted to mine and agency personnel in all permit areas. Specific road closures would include the Little Cherry Loop Road (NFS road #6212) within the proposed Little Cherry Creek Tailings Impoundment Site, the Poorman Creek Road (NFS road #2317) in the lower portion of the Poorman Creek drainage, and NFS road #4784 in the Bear Creek drainage (which is already proposed for an access change as part of the Rock Creek Project mitigation). The South Fork Miller Creek road (NFS road #4724) would be closed on a seasonal basis.

Before mine operations, Libby Creek Road (NFS road #231) and Upper Libby Creek Road NFS road #2316 would be continue to be plowed in the winter as part of a 2-year Libby Adit evaluation program and a 1-year Bear Creek Road (NFS road #278) reconstruction. The improvements to the Bear Creek Road would improve recreational access to the area and would safely accommodate mine-related and public traffic. Because the Bear Creek Road would be plowed in the winter, its use would improve winter recreation access to areas near the road. Similarly, the Libby Creek Road would be plowed for 2 to 3 years during construction, improving winter recreation access to areas off of the road. Snowmobile and cross country skiing use of the Libby Creek Road and parts of Upper Libby Creek Road during the Evaluation and Construction Phases, and of the Bear Creek Road during the Operations Phase, would be eliminated.

Access restrictions at the permit area boundary of each mine facility would eliminate access to all roads within the permit boundary that are currently closed to motorized use but open to non-motorized use. These closures would eliminate all public recreation access to the Poorman Creek and Ramsey Creek drainages (NFS road #2317 and NFS road #4781, respectively) (Figure 17). Similarly, non-motorized access to existing trails in the Poorman Creek (Trail 129) and Ramsey Creek (Trail 820) would be lost. Non-motorized trail access up the Libby Creek drainage (Trail 119) would not be affected (trail locations are shown on Figure 80).

The overall character of the trail user experience would be altered in the Libby Creek drainage due to noise, traffic, and visual effects associated with the proposed facilities. Within the CMW and the adjacent Cabinet Face East IRA, the recreational enjoyment of trails, lakes, and overall wilderness values in the upper Ramsey Creek drainage may be adversely affected due to the construction, operation, and reclamation of the Ramsey Plant Site. Visual effects on user experience due to the construction and operation of proposed facilities are described in section 3.17, *Scenery*. The proposed Rock Lake Ventilation Adit, located east of Rock Lake on a small parcel of private land outside of the CMW, would potentially be visible from some locations within the CMW. The surface features at the ventilation shaft and the overall effect of those features would be minimal and would not affect recreation. The Howard Lake Campground and the Libby Creek Recreational Gold Panning Area would not be directly affected by any of the proposed facilities or road closures, but these and other recreation resources may be subject to increased use due to better road access and familiarity among mine employees in the area.

In Alternative 2, Little Cherry Creek would be diverted in a permanent Diversion Channel around the impoundment. Most of the diversion would be within the operating permit area for the tailings impoundment, and access would be restricted. The KNF and the FWP estimated a loss of 383 angler-hours of recreational fishing opportunity. The fisheries mitigation proposed by MMC in Alternative 2 was identified in the KNF's 1993 ROD (USDA Forest Service 1993) as adequate mitigation for the loss of recreational opportunity. The 1992 Final EIS effects analysis and 1993 ROD mitigation did not consider the likely need for a pumpback well system to prevent tailings seepage from reaching surface water. Flow in the diverted Little Cherry Creek would be substantially reduced during operations and closure, as the pumpback well system, as long as it operated, would likely eliminate very low flow in the diverted creek. The loss of available habitat in the diverted Little Cherry Creek would adversely affect the redband trout population in the diverted creek because the remaining habitat would not support the population at its current numbers, if at all.

3.16.4.2.2 Changes to Recreation Setting

During mine operations, the level of mine facility development proposed in Alternative 2 would change the ROS classes for some portions of the analysis area (Table 147). The Ramsey Creek drainage within the analysis area would change from Semi-Primitive Motorized to Rural in character. The Little Cherry Creek drainage and most of the Libby Creek drainage would primarily change from Roaded Natural to Rural (the upper portions of the Libby Creek drainage, west of the adit site, would remain Semi-Primitive Motorized). As in all action alternatives, the Bear Creek Road (NFS road #278) corridor would remain Roaded Natural from US 2 to the

Table 147. Estimated Change in Acres of ROS Class within the Mine and Transmission Line Analysis Area.

ROS Class	Rural		Roaded Natural		Semi-Primitive Motorized		Semi-Primitive Non-Motorized	
	Acres	% change	Acres	% change	Acres	% change	Acres	% change

Notes: ROS categories of Primitive and Roaded Modified were not identified in the analysis area and are not shown in this table. Total analysis area is 72,441 acres.
% increase in rural ROS setting during Construction is meaningless as existing Rural ROS is 0 acres.
Source: GIS analysis by ERO Resources Corp. using KNF ROS delineation procedures.

impoundment site, and would change to Rural near the impoundment site, LAD Areas, and plant site.

These changes from less developed to more developed recreation settings would likely displace some recreationists seeking a more remote and dispersed recreation experiences. Most of the Libby Creek Road (NFS road #231) would remain as Roaded Natural, except for small portions nearest the mine facilities that would change to Rural. The changes in ROS in the mine area during the Construction Phase would continue during the Operations Phase.

3.16.4.2.3 Long-term Effects After Closure

The long-term effects on recreation after completion of mine operations and reclamation include the elimination or closure of several roads within the permit boundary. Motorized access to the Little Cherry Creek Loop road (NFS road #6212) within the Little Cherry Creek Tailings Impoundment Site would change due to the tailings impoundment, reducing motorized access for scenic driving, hunting, fishing, and other uses.

Over the long term, public access would be restored to portions of NFS road #5182 through the Little Cherry Creek Tailings Impoundment Site and NFS road #4781 through LAD Area 2. The restoration of access along NFS road #4781 would provide long-term motorized access to the Poorman Creek drainage (NFS road #2317/Trail 129) and both motorized and non-motorized access to the Ramsey Creek drainage (motorized access along NFS road #4781 and non-motorized access to Trail 820).

No long-term effects on trail-user access or experiences in the CMW, the Howard Lake Campground, and the Libby Creek Recreational Gold Panning Area would occur. T the long-term ROS classes throughout the analysis area would return to preexisting categories as disturbed areas became successfully revegetated and tree cover returned to pre-mine conditions (see descriptions of reclamation and revegetation plans in Chapter 2). The increased access and familiarity of the area for recreation would likely displace current dispersed users in and around the analysis area.

Flow in the diverted Little Cherry Creek would likely be eliminated if a pumpback well system was installed and continued to operate. The diverted creek would not be capable of supporting redband trout. Flow from the tailings impoundment at closure would be directed toward Bear Creek, with flow in the diverted Little Cherry Creek estimated to be 45 percent less than existing flow. Reestablishment of the redband trout population in Little Cherry Creek would not likely occur after the pumpback wells ceased operating and flows increased. Recreational fishing opportunity in the diverted creek would be eliminated or substantially reduced. MMC's proposed mitigation would partially offset the loss of fishing opportunity.

3.16.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

3.16.4.3.1 Short-term Effects During Construction, Operations, and Closure Phases

The overall short-term effects of Alternative 3 on recreation would be similar to Alternative 2, except as discussed below. Public motorized and non-motorized access would be restricted to mine and agency personnel in all permit areas.

Noise levels between 45 and 55 dBA from the Libby Plant Site may adversely affect recreational use and enjoyment of the Libby Creek Recreational Gold Panning Area (see section 3.20.4, *Environmental Consequences* of the *Sound, Electrical and Magnetic Fields, Radio and TV Effects* section). Visual effects on user experience due to the construction and operation of proposed facilities are described in section 3.17.4, *Environmental Consequences* of the *Scenery* section.

The specific configuration of the Little Cherry Loop Road (NFS road #6212) closure and other road closures within the proposed Poorman Tailings Impoundment Site would be different from Alternative 2, but the effect of the closures (restricting both motorized and non-motorized recreation access) would be the same.

Non-motorized recreation and trail access to the upper Poorman Creek drainage (NFS road #2317/Trail 129) would be retained and improved due to the development of a recreational parking area adjacent to LAD Area 1 along Poorman Creek Road (NFS road #2317). The recreational enjoyment of the Libby Creek Trail (Trail 119), west of the Libby Adit Site, and overall wilderness values in the CMW would be altered in the upper Libby Creek drainage due to noise, traffic, and visual effects associated with the proposed facilities in the Libby Creek drainage. Unlike Alternative 2, non-motorized recreation access would be permitted through the permit area boundary on NFS road #4781/Trail 820 to the upper Ramsey Creek drainage. The improvements to the Bear Creek Road (NFS road #278) would improve recreational access to the area. Because the Bear Creek Road would be plowed in the winter, it would improve winter recreation access to the analysis area (although the existing snowmobile use of the road would be affected).

In Alternatives 3 and 4, MMC would fund access changes on numerous roads for wildlife mitigation (see Table 28 and Table 29 in Chapter 2). Seven roads totaling 14.8 miles that are currently open would be barriered year-long. Four roads totaling 9.3 miles would be gated seasonally between April 1 and June 15. In addition, MMC would decommission or place into intermittent stored service NFS road #4784 (upper Bear Creek Road) if the Rock Creek Mine mitigation restricting the road with a barrier had not been implemented before Forest Service authorization to initiate the Evaluation Phase. These closures would eliminate motorized recreational access and use, such as camping and hunting, in these locations, but would not affect the overall quality or accessibility or recreation in the analysis area. Non-motorized access would be maintained. Other access changes, such as changing access restrictions from a gate to a barrier or converting restricted roads to trails, would not affect recreation access. The development of a scenic overlook along the Bear Creek Road (NFS road #231) downstream of the Midas Creek crossing with views of the tailings impoundment and interpretive information about the mine would benefit recreation opportunities by providing an additional amenity in the area. Overall recreation effects would be mitigated through funding a campground host from Memorial Day through Labor Day at Howard Lake Campground during the Construction and Operations Phases of the mine.

The agencies' proposed water resources monitoring would require monitoring of water resources in the East Fork Rock Creek, East Fork Bull River, and Swamp Creek drainages (see Appendix C). Increased use by project personnel conducting the monitoring would decrease opportunities for solitude or a primitive and unconfined type of recreation in the East Fork Rock Creek, East Fork Bull River, and Swamp Creek drainages.

Channels affected by the Poorman Tailings Impoundment Site are not fish-bearing and do not provide recreational fishing access. Alternative 3 would not affect recreational fishing opportunities.

3.16.4.3.2 Changes to Recreation Setting

The level of mine facility development proposed in Alternative 3 would change the ROS classes for the analysis area (Table 147). Most of the Libby Creek drainage within the analysis area would change in character from Roaded Natural to Rural, while the upper portions of the drainage would change from Semi-Primitive Motorized to Semi-Primitive Non-Motorized due to road closures. Likewise, most of the Ramsey, Poorman, and Bear Creek drainages would change to Semi-Primitive Non-Motorized due to road closures. A permanent increase of 8,200 to 9,200 acres, depending on the transmission line alternative, would occur in the Semi-Primitive Non-Motorized class.

Most of the decrease would be in the Semi-Primitive Motorized class, which would decrease between 8,400 and 9,000 acres, depending on the transmission line alternative. The southern portion of the Little Cherry Creek drainage would change from Roaded Natural to Rural. As in all action alternatives, the NFS road #278 corridor would not change (Roaded Natural) from US 2 to the impoundment site, but would change to Rural near the impoundment site, LAD Areas, and plant site. The changes in ROS in the mine area during the Construction Phase would continue during the Operations Phase.

Changes from less developed to more developed recreation settings near the mine development facilities would likely displace some recreationists seeking a more remote and dispersed recreation experience, but those types of experiences would be increased in most of the upper drainages that would change to a less developed, non-motorized recreation setting.

3.16.4.3.3 Long-term Effects After Closure

The long-term effects of the mine operations, after closure and reclamation are complete, would include the elimination of several roads within the tailings impoundment site, including NFS road #6212.

Long-term recreational access to the roads and trails in the Poorman, Ramsey, and Libby Creek drainages would be similar to existing conditions. Roads and trails closed for wildlife mitigation would no longer be used for motorized access. No long-term effects on trail-user access or experiences in the CMW, the Howard Lake Campground, and the Libby Creek Recreational Gold Panning Area would occur. New recreation amenities, including a recreational parking area along Poorman Creek Road (NFS road #2317) and a scenic overlook along Libby Creek Road (NFS road #231) would provide long-term recreation benefits. A permanent increase of 9,500 to 9,700 acres, depending on the transmission line alternative, would occur in Semi-Primitive Non-Motorized characteristics.

3.16.4.4 Effectiveness of Agencies' Proposed Mitigation

While the effects of the mine alternatives would result in the loss of some recreation opportunities and aesthetic changes near mine facilities, the proposed mitigation measures would mitigate some of the impacts on recreation. These measures include:

- Construction of a scenic overlook with interpretive signs with views of the tailings impoundment on NFS road #231 would provide an amenity for visitors who are curious about or interested in the function and purpose of the mine.

- Pay the reimbursement funding for a volunteer campground host from Memorial Day through Labor Day at Howard Lake campground using an Volunteer Services Agreement for Natural Resources agencies (Optional Form 301a) throughout the life of the project would enhance the level of service and quality of the experience for campground guests, potentially offsetting some of the aesthetic impacts of the nearby mine.
- Inspection and maintenance of access changes (e.g., road and trail closures) would help ensure that appropriate visitor access is safe and easily understood.
- Development of a small parking area along Poorman Creek Road would offset some of the road and trail closures by proving a new amenity and giving visitors a clear transition point between the road closure and new or existing trail access opportunities.
- Development of a new hiking trail between Poorman and Ramsey Creeks would provide non-motorized access to upper Ramsey Creek which would offset some of the effects of road closures and may provide new non-motorized recreation opportunities.

During operations, these mitigation measures would be effective in reducing the impact on the mine on some recreationists. These measures would not address the effects on all visitors, due to the individual nature of dispersed recreation in and near the analysis area.

3.16.4.5 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

The effects of the plant site, adits, and LAD Areas in Alternative 4 on recreation and recreation setting would be the same as those described under Alternative 3. The effects of the tailings impoundment in Alternative 4 on recreation would be the same as those described under Alternative 2. Additional fisheries mitigation would compensate for all lost aquatic habitat and recreational fishing opportunity in diverted Little Cherry Creek. The long-term effect on ROS classes would be the similar to Alternative 3. Proposed mitigation would be the same as Alternative 3. A permanent increase of 9,500 acres would occur in Semi-Primitive Non-Motorized class. Most of the decrease would be in the Semi-Primitive Motorized class, which would decrease between 8,400 and 9,000 acres, depending on the transmission line alternative.

3.16.4.6 Alternative A – No Transmission Line

Alternative A would not affect recreation in the analysis area. Access to roads and trails would continue as it is currently. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. The Sedlak Park Substation and the loop line to BPA's Noxon-Libby line would not be constructed.

3.16.4.7 Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

The North Miller Creek Alternative would have the greatest amount of new access roads (10.2 miles) for the construction and maintenance of the transmission line (Table 143). These roads would be closed to motorized vehicles. These new roads would benefit non-motorized recreation access (*i.e.*, walk-in hunting and fishing access, hiking, berry picking) on both National Forest System lands and on private lands where public access was permitted.

Alternative B would cross through the Libby Creek Recreational Gold Panning Area for a distance of 1,760 feet, and also would cross Trails 118, 716, and 820 (Figure 80). Transmission line construction would adversely affect the short-term use and enjoyment of these areas due to increased noise, traffic, and construction activity. During mine operations, the existence of the transmission line would alter the scenic integrity and landscape character of trail corridors and the Gold Panning Area. The alteration of scenic integrity in these localized areas would have minor adverse effects on enjoyment of recreational amenities that would be crossed by the transmission line. Alternative B would not be visible from Howard Lake and would have no effect on Howard Lake recreation.

The ROS classes of most of the transmission line corridor would not change, except for a segment of Semi-Primitive Motorized that would change to Roaded Natural in the area north of Miller Creek. This change from a less developed to a more developed recreation setting may displace some recreationists seeking a more remote and dispersed recreation experience. The ROS change would return to existing conditions (Semi-Primitive Motorized) after the transmission line was constructed, but would be affected again when the transmission line was removed at the end of operations. Over the long term, the ROS classes in this area would return to existing conditions (Semi-Primitive Motorized).

Construction of the Sedlak Park Substation and the loop line to BPA's Noxon-Libby line would not adversely affect recreation. Both would be located on private land.

3.16.4.8 Alternative C-R – Modified North Miller Creek Transmission Line Alternative

Alternative C-R would benefit non-motorized recreation access by providing 3 miles of new access roads on both National Forest System and private lands where public access is permitted (Table 143). These new road corridors would enhance non-motorized recreation access. The length of new roads in Alternative C-R (and subsequent recreation benefits) would be the least among the transmission line alternatives. Alternative C-R would cross trails 65, 118, 716, and 859 (Figure 80), as well as the Libby Creek Recreational Gold Panning Area for a distance of 1,750 feet. The adverse effects on trails and the Gold Panning Area would be the same as Alternative B. Alternative C-R would not be visible from Howard Lake and would have no effect on Howard Lake recreation.

The ROS classes of most of the transmission line corridor would not change, except for a segment of Semi-Primitive Motorized that would change to Roaded Natural in the area north of Miller Creek. This change from a less developed to a more developed recreation setting may displace some recreationists seeking a more remote and dispersed recreation experience. The ROS change would be similar to existing conditions (Semi-Primitive Motorized and Semi-Primitive Non-Motorized) after the transmission line was constructed, but would be affected again when the transmission line was removed at the end of operations. Over the long term, the ROS classes in most of this area would return to existing conditions (Semi-Primitive Motorized), while some of the area would change to a less developed setting of Semi-Primitive Non-Motorized.

Construction of the Sedlak Park Substation and the loop line to BPA's Noxon-Libby line would not adversely affect recreation. Both would be located on private land.

3.16.4.9 Alternative D-R – Miller Creek Transmission Line Alternative

Alternative D-R would have more miles (5.1 miles) of new access roads (and related benefits to non-motorized recreation access) than Alternative C-R. Alternative D-R would cross trails 65, 300, 505, 716, and 859, (Figure 80), as well as the Libby Creek Recreational Gold Panning Area for a distance of 2,120 feet. The effects on trails and the Gold Panning Area would be the same as Alternative B. About 0.4 miles of the Alternative D-R transmission line corridor would be visible from Howard Lake. Such visual effects may diminish the quality of the recreation experience for some visitors.

The ROS classes of most the transmission line corridor would not change, except for a small segment near the eastern edge that would change from Semi-Primitive Non-Motorized to Roaded Natural. This change from a less developed to a more developed recreation setting may displace some recreationists seeking a more remote and dispersed recreation experience. The ROS change would return to existing conditions (Semi-Primitive Motorized) after the transmission line was constructed, but would be affected again when the transmission line was removed at the end of operations. Over the long term, the ROS classes in this area would return to existing conditions (Semi-Primitive Motorized).

Construction of the Sedlak Park Substation and the loop line to BPA's Noxon-Libby line would not adversely affect recreation. Both would be located on private land.

3.16.4.10 Alternative E-R – West Fisher Creek Transmission Line Alternative

The length of new access roads in Alternative E-R (and related benefits to non-motorized recreation access) (4.0 miles) would be greater than Alternative C-R, but less than Alternative B and D. Alternative E-R would cross trails 65, 505, 716, and 859 (Figure 80), as well as the Libby Creek Recreational Gold Panning Area for a distance of 2,120 feet. The effects on trails and the Gold Panning Area would be the same as Alternative B. About 0.4 miles of the Alternative E-R transmission line corridor would be highly visible from Howard Lake. Such visual effects may diminish the quality of the recreation experience for some visitors. These changes would not substantially affect the ROS classes.

Construction of the Sedlak Park Substation and the loop line to BPA's Noxon-Libby line would not adversely affect recreation. Both would be located on private land.

3.16.4.11 Cumulative Effects

Past actions within the analysis area include the establishment of forest access roads and logging roads and the development of the Howard Lake Campground and Libby Creek Recreational Gold Panning Area. These past actions have resulted in the existing recreation setting described above under section 3.16.3, *Affected Environment*. Population increases due to these projects would slightly increase demand for recreational opportunities in the region. Even with this increased demand, an abundance of outdoor recreational opportunities would remain for residents and visitors.

3.16.4.12 Regulatory/Forest Plan Consistency

All of the proposed mine and transmission line alternatives would be consistent with the recreation standards in the KFP. The effect of the mine and transmission line alternatives on the ROS classes is disclosed. This analysis complies with Executive Order 12962 that mandates disclosure of effects on recreational fishing.

3.16.4.13 Irreversible and Irretrievable Commitments

The recreational experience of some users may be irretrievably affected by the project, due to loss of access to particular areas, increased noise, or visual impacts. These effects, combined with increased knowledge of and access to the general analysis area, would likely displace some dispersed recreation (hunting, hiking, and dispersed camping) to other areas of the forest. Long-term road closures within the tailings impoundment and other areas for grizzly bear mitigation in all action alternatives would result in an irretrievable loss of recreational access.

3.16.4.14 Short-term Uses and Long-term Productivity

All of the action alternatives would include both short-term and long-term road closures within the permit boundary. Short-term closures would have the greatest effect on recreation access in Alternative 2, which would restrict access to the Ramsey and Poorman creek drainages. Long-term road closures in all action alternatives would reduce recreation access within and adjacent to the tailings impoundment. The long-term effects of the proposed project on recreation access in the analysis area would be small.

The noise and visual effects of the proposed project would be most noticeable during the 16 to 19 years of operations. Noise would return to pre-mine levels when reclamation activities ceased, while visual effects would be reduced over time as revegetation efforts were completed and the forest cover re-established in disturbed areas. Over the long term, the proposed project would not affect the ability of the analysis area to provide a variety of forest recreation opportunities.

3.16.4.15 Unavoidable Adverse Environmental Effects

Alternatives 2, 3, and 4 would restrict access and recreational use along the Little Cherry Creek Loop Road (NFS road #6212), which would be restricted to public motorized and non-motorized access. Alternative 2 would restrict recreational access to the Ramsey Creek and Poorman Creek drainages. In addition, all of the proposed transmission line alternatives would alter the scenic integrity of the Libby Creek Recreational Gold Panning Area, as well as several trail corridors. The proposed mine alternatives would adversely affect some recreational experiences due to noise and visual impacts. These aesthetic impacts would be concentrated in the Ramsey and Libby creek drainages in Alternative 2, the Libby Creek drainage in Alternatives 3 and 4, and along NFS road #278 (Tailings Impoundment Sites) in all mine alternatives.

3.17 Scenery

3.17.1 Regulatory Framework

The Organic Administration Act authorizes the Forest Service to regulate the occupancy and use of National Forest System lands. The Forest Service's locatable minerals regulations are promulgated at 36 CFR 228, Subpart A. The regulations apply to operations conducted under the U.S. mining laws as they affect surface resources on National Forest System lands under the jurisdiction of the Secretary of Agriculture. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources. 36 CFR 228.8 also requires that mining operators to the extent practicable, harmonize operations with scenic values through such measures as the design and location of operating facilities, including roads and other means of access, vegetation screening of operations, and construction of structures and improvements which blend with the landscape (36 CFR 228.8(d)).

Under the current KFP, the KNF uses the USDA Forest Service Visual Management System (VMS) to inventory visual resources and to provide measurable scenery management standards on the KNF (USDA Forest Service 1974). VQOs were determined by the KNF for the entire KNF following an analysis of characteristic landscapes and sensitivity levels. The five VQOs are: Preservation, Retention, Partial Retention, Modification, and Maximum Modification; these terms are defined in the *Glossary*. Development of measurable standards or objectives for the visual management is the purpose of assigning VQOs. Each VQO describes a degree of acceptable alteration of a characteristic landscape based on the importance of aesthetic resources to the users. VQOs are an important part of the KFP because many national forest users and nearby residents value the forest's intrinsic aesthetic resources.

In mine Alternatives 2, 3, and 4, the KNF would amend the KFP by reallocating to MA 31 all areas within the operating permit areas of LAD Areas 1 and 2, and portions of the plant site and tailings impoundment currently not in MA 31. MA designations, goals, and standards are described in detail in Table 138. In addition, a proposed road and facility corridor that would cross MA 13 would be reallocated to MA 31. MA 31 has a VQO of Maximum Modification. Therefore, the applicable VQO for all mine facilities would be Maximum Modification. In transmission line Alternatives B, C-R, D-R, and E-R, the KNF would amend the KFP by reallocating certain areas disturbed by the 230-kV transmission line on National Forest System lands as MA 23. MA 23 has a VQO of Maximum Modification. The MAs that would not be reallocated to MA 23 currently have a VQO of Modification. The applicable VQO for all transmission line alternatives would be Maximum Modification or Modification.

3.17.2 Analysis Area and Methods

3.17.2.1 Analysis Area

The analysis area was determined by the location of the proposed mine facilities, the location of four transmission line alternatives and the visible portions of proposed project facilities that would affect the characteristic landscapes and sensitivity levels of observation points used in visual baseline reports. Changes to characteristic landscapes would include loss of vegetation and landform modifications at and near the proposed facilities, and sensitivity levels would be lowered by the presence of mine facilities not already existing within a given view. Scenery in the analysis area includes the summit and shoulder terrain of the Cabinet Mountains, forested mountains, and valleys adjacent to and east of the Cabinet Mountains; and a 6-mile portion of US 2 east of the Cabinet Mountains (Figure 82).

3.17.2.2 Methods

Several previous visual resource reports and additional analysis were used to describe and assess effects on scenery. MMC assessed visual resources near the mine facilities alternatives, excluding the transmission line alternatives, in 2005 (Maxim Technologies.2005). The report assessed the visual effects of proposed mine facilities using two USDA Forest Service methods for analysis. Both methods used KNF user data and observation points from a previous visual resource baseline study (Woodward-Clyde Consultants 1989d).

Several transmission line alternatives developed by MMC for its MFSA certificate application were assessed in a visual impacts report (Power Engineers, Inc. 2006b). The report used the same two methods as the Maxim Technologies report to analyze visual impacts.

In addition to the use of previous visual resources reports, the lead agencies assessed current mine and transmission line alternatives from 11 key observation points (KOP) selected by the KNF and DEQ (Holdeman Landscape Architecture 2006). KOP selection and landscape character regions were determined during a site visit in 2006. Criteria for KOP selection was based on recreational uses of specific KNF roads, scenic overlooks, and Howard Lake (Table 148). The USDA Forest Service VMS method was used to describe impacts on scenery for the mine facilities alternatives. The VMS method of analysis directly associated project impacts on applicable VQOs.

Table 148. Reasons for Selecting KOPs.

KOP	Reason for Selection	KOP	Reason for Selection
1	High use NFS road with a parking pullout	7	High use NFS road
2	High use scenic overlook with unobstructed views of Cabinet Mountains	8	High use NFS road
3	Hiking trail destination at the top of Elephant Peak	9	Intersection of two high use roads (NFS road and U.S. highway)
4	High use NFS road with a parking pullout and scenic overlook sign	10	High use U.S. highway
5	High use Howard Lake boat ramp	11	Permanent residences
6	High use NFS road		

Visual analysis of the transmission line alternatives consisted of two viewshed analyses. One viewshed analysis was performed from each of the 11 KOPs. Vegetation was included in the analysis by adding an average tree height to the digital terrain model to determine the length of each transmission line alternative visible from each KOP. Different tree heights were estimated for timber harvested areas from KNF data identifying the dates of harvesting. Digital polygons were developed to represent the shape of the tree clearing areas required for the lines, structures, and access roads. The digital polygons were “elevated” electronically above the ground to the various tree heights. The total length of transmission line alternative visible from each KOP was determined using GIS. A qualitative analysis is also provided regarding the level and type of use at each KOP. The qualitative analysis was developed from field observations and photographic simulations from four of the 11 KOPs (Figure 82).

The second viewshed analysis was performed from the corridor of each transmission line alternative. The same polygons used in the first analysis were used in the second one. This analysis determined the number of KOPs, length of high-use roads, and acres of CMW visible from each transmission line corridor. Roads used in the analysis were NFS roads #4776, #4724, #231, #385, and US 2.

The visibility of the transmission line from the Howard Lake Campground was evaluated in two transmission line alternatives, Miller Creek and West Fisher Creek. These two alternatives would use the same alignment east of the lake and campground. Using digital elevation data, a profile of the ground surface was developed for each transmission line structure near the lake. Trees 75 feet high between the viewer on the west side of the lake and the transmission line were used to determine line visibility. The analysis is on file in the project record.

3.17.3 Affected Environment

The analysis area is characterized visually by the summit peaks of the Cabinet Mountains surrounded by the adjacent densely forested mountains and valleys, with some flat, open creek or stream valleys of dense low-growing herbaceous vegetation interspersed with the forest. The four transmission line alternatives and mine facilities alternatives would be located in montane forest and valley characteristic landscapes within the KNF. Multiple alpine peaks in the Cabinet Mountains are also an important part of views from most of the key observation points. Current sources of night lighting are activities at the Libby Adit and limited residential development on private land.

3.17.3.1 Landscape Character

An area's appearance, called landscape character, is based on the area's physical characteristics, includes the visible combination of physical, biological, and cultural attributes. An existing landscape character may range from predominantly natural landscapes to those heavily influenced by cultural features. The existing landscape character description includes the natural scenic attributes of the landscape in combination with the existing land use pattern. Three identifiable landscape characters are found in the analysis area: alpine, montane forest, and montane valley as described in the following sections.

3.17.3.1.1 Alpine Landscape Character

The alpine landscape character is defined by a portion of the Cabinet Mountains along a north-south line from Snowshoe Peak to Baree Mountain (about 35 miles long and 7 miles wide), centered along the range's highest peaks; and includes some mountainous areas below timberline known as the Cabinet Shoulders. Mountain summit landforms with dominant vertical and steep slopes above timberline typify the alpine characteristic landscape. Near mountaintops and above timberline, areas of snow are frequently present. The summit topography possesses strong contrasting characteristics with the sky and landforms below.

The mountain slopes below and near timberline support sparse populations of evergreen trees with a ground cover of shrubs and grasses. The forested portion of the alpine characteristic landscape also includes large, mostly bare rock formations, creating many open areas among the trees. This region has the highest elevations (8,738 feet at Snowshoe Peak) in the analysis area.

Although no mine facilities or transmission line alternatives would be located in the alpine characteristic landscape, one KOP is located in this area. Additionally, this characteristic landscape is an important component of the views from most of the other KOPs. This characteristic landscape is the highest quality scenery as defined by the VMS.

The KOP in the alpine characteristic landscape is located on Elephant Peak in the CMW. Views from this location are unobstructed in nearly all directions; are mostly absent of artificial forms; and include a large variety of landforms, rock forms, water forms, colors, and textures. The views from this KOP are representative of most of the Cabinet Mountains peaks and some of the CMW above timberline. Most of the proposed mine facilities, not including the tailings impoundments, and portions of all four transmission line alternatives would be visible from this KOP.

3.17.3.1.2 Montane Forest Landscape Character

Most mine and transmission line alternatives would be located in the montane forest landscape character. Densely forested mountain landforms typify this landscape. Due to the high density and the height of the forest near roads, only a small number of long-distance views exist from roads. Most views along roads are of the forest and restricted to short distances.

The analysis area has few developed recreational facilities; most observation points are from roads, mountains, and hill tops, or at the edge of the forest. An exception is the developed campground area at Howard Lake, which has a KOP located on the beach next to the lake. Timber harvest areas have created some openings in the forest along roads that provide views of the Cabinet Mountain summits and valleys below. These few locations offer tree-framed views with a large variety of mountainous landforms, vegetation communities, and sky conditions. KOPs 1, 2, 4, and 6 are located in montane forests.

3.17.3.1.3 Montane Valley Landscape Character

Gentle to nearly flat landforms with creeks or streams define the montane valley landscape character, which is interspersed within the montane forest characteristic landscape. Some mine facilities and transmission line alternatives would be located in the montane valley characteristic landscape. Montane valleys include forested areas similar to the adjacent mountains and openings with low-growing herbaceous vegetation and deciduous shrubs and trees concentrated along creeks. Views of the Cabinet Mountain summits are visible from the valleys with low-growing vegetation. Valley areas also include the only buildings visible from KOPs in the analysis area. All of the buildings are residences or associated outbuildings, and most of the residences are located along US 2. Due to the relatively small quantity, very low density, and partial obscurity by low density vegetation, these structures rarely distract from scenic views by travelers and other recreationists.

Some timber harvest areas of the KNF and adjacent private lands are visible from KOPs located in montane valleys. A few timber harvest areas are immediately adjacent to the public roads and are therefore highly visible. Timber harvest areas on mountainsides are typically only partially visible due to the screening effects of vegetation and topography. KOPs 7, 8, 9, 10, and 11 are located in montane valleys.

3.17.3.2 Concern Levels and Visibility

Concern levels, from low to high, were established from user survey information for individual observation points to determine the importance of visual resources to the visitors. Concern levels of visitors were identified from visitor use monitoring data collected by the KNF (Kocis *et al.* 2003). The largest groups of visitors to the KNF are local residents from the towns of Libby, Troy, and Eureka. Forest scenery consistently ranked highest in importance for wilderness, developed day use areas, overnight facility users, and some private residences with views of proposed facilities. Concern levels at private residences in the analysis area are high. Views from private residences are typically long-term and often influence specific uses of private properties.

3.17.3.3 Visual Quality Objectives

Areas currently managed for Partial Retention, Modification and Maximum Modification VQO comprise most of the analysis area (Figure 81). The LAD Areas, Poorman Impoundment Site and transmission line corridors primarily have a Modification VQO. To meet the Modification VQO, management activities may visually dominate the characteristic landscape (Table 149). With a Modification VQO, activities of vegetation and/or landform alteration must borrow from the existing undisturbed form, line, color, and texture so as to match the surrounding characteristic landscape. Portions of the Ramsey Plant Site, Little Cherry Creek Impoundment Site, and the south side of Miller Creek along the transmission line corridors have a Maximum Modification

Table 149. VQO Definitions.

VQO Class	Description of Management Prescription
Preservation	Areas managed to meet VQO of Preservation allow ecological changes only. Management activities, except for very low visual impact recreation facilities, are prohibited.
Retention	Areas managed to meet VQO of Retention provide for management activities that are not visually evident. Activities may only repeat form, line, color, and texture which are frequently found in the characteristic landscape. Changes in the qualities of size, amount, intensity, direction, and pattern should not be evident.
Partial Retention	Areas managed to meet VQO of Partial Retention permit management activities that remain visually subordinate to the characteristic landscape. Activities may repeat form, line, color, or texture common to the characteristic landscape, and may also introduce form, line, color, or texture which are found infrequently or not at all in the characteristic landscape.
Modification	Areas managed to meet VQO of Modification allow management activities that may visually dominate the original characteristic landscape. However, activities of vegetative and landform alteration must borrow from naturally established form, line, color, or texture so completely and at such a scale that its visual characteristics are those of natural occurrences with the surrounding area or character type.
Maximum Modification	Areas managed to meet VQO of Maximum Modification permit management activities of vegetative and landform alterations that may dominate the characteristic landscape. However, when viewed as a background, the visual characteristics must be those of natural occurrences with the surrounding area or character type. When viewed as foreground or middleground, they may not appear to completely borrow from naturally established form, line, color, or texture. Alterations may also be out of scale or contain detail that is incongruent with natural occurrences as seen in foreground or middleground.

Source: USDA Forest Service 1974.

VQO. Management activities may dominate the characteristic landscape in a Maximum Modification VQO. Small areas of Partial Retention VQO are found in the mine area and along the transmission line corridors.

3.17.4 Environmental Consequences

3.17.4.1 Alternative 1 – No Mine

The existing scenery from KOPs and acreage of existing VQOs would not change in the No Mine Alternative. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150, would remain in effect. The DEQ's approval of revisions to DEQ Operating Permit #00150 (Minor Revisions 06-001 and 06-002) also would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. The existing Libby Adit Site disturbances would remain, and would be visible only from KOP 4 in a montane forest at a NFS road #231 Pullout (Figure 82). Disturbances on private land at the Libby Adit Site would remain until reclaimed in accordance with existing permits and approvals.

3.17.4.2 Alternative 2 – MMC's Proposed Mine

For all action alternatives, and for the duration of the mine's and transmission line's operations, mine facilities, presence of haul vehicles, and introduction of night lighting at all mine facilities and along NFS roads would alter views from KOPs and other locations. Following mine closure, reclamation of most mine facilities would return disturbed areas to a condition similar to a timber harvested area. The tailings impoundment would not be restored to match any existing condition in the KNF and would result in a permanent change in scenery.

The widening and paving of Bear Creek Road would be evident but remain visually subordinate to the surrounding area because a road exists at the same location. The new Bear Creek Road would noticeably alter scenic integrity from forest visitors on the road. The creation of a new access road between the impoundment site and LAD areas would noticeably alter the line, color, texture, and form of the existing forest. The new access road would be highly evident from KOPs 2 and 3, some other KNF locations.

3.17.4.2.1 Libby Adit Site and Rock Lake Ventilation Adit

The entire existing disturbance at the Libby Adit Site is on private land and new disturbance at the site in all mine alternatives would be minimal. Activity at the site would increase during all mine phases in all mine alternatives. The existing Libby Adit Site would continue to alter scenic integrity from the scenic overlook at KOP 2, Elephant Peak (KOP 3), the south NFS road #231 pullout (KOP 4), a portion of NFS roads #231 and #4776, portions of the CMW, and a portion of a private land parcel along Libby Creek northeast of the adit site (Figure 82). Viewing significance, as defined by the VMS Concern Levels from the three KOPs and two roads would be high due to high visitor use and long viewing duration due to stationary viewers or a high viewing angle above the site's location. The visible landscape character would be changed through landform modifications and vegetation pattern interruptions. The change would alter scenic integrity by introducing noticeable contrasts of new buildings, fencing, night lighting, and the presence of mine traffic. The visual absorption level of the Libby Adit Site is high, indicating a substantial capacity to accommodate change. Noticeable changes from KOP 4 would be substantial due to a direct unobstructed line of sight to the adit and long duration views. Because of the screening effects of trees and topography, a relatively small portion of the adit site would remain visible from a private land parcel southeast of the site. Because the Libby Adit Site is and the Rock Lake Ventilation Adit would be located on private land, no VQO criteria apply. Following the mine closure, regrading and revegetation would create areas with similar landscape characteristics to the existing timber harvested areas and unpaved, abandoned roads.

The Rock Lake Ventilation Adit would be an air ventilation opening on the ground, about 15 feet by 15 feet in size, and covered by a metal grate. No mine materials would be transferred to or from this location, and a temporary construction disturbance would be limited (less than 1 acre) because the adit would be constructed from the mine underground. The adit would be located on the west side of the Cabinet Mountains and, therefore, not visible from 10 of the 11 KOPs. The adit would be very difficult to see from KOP 3, Elephant Peak, because of the site's relatively small size and the screening effects of topography. Some views of the adit from Rock Lake would be partially obscured by topography and timberline vegetation. Following the mine closure, regrading would create an area with similar landscape characteristics to the existing treeless areas at timberline.

3.17.4.2.2 Ramsey Plant Site

Construction and use of the Ramsey Plant Site would alter the scenic integrity from the scenic overlook at KOP 2, Elephant Peak (KOP 3), a portion of NFS roads #231 and #4776C, and portions of the CMW (Figure 82). Viewing significance would be high due to high visitor use along NFS road #4776C and at KOP 2, and the high view angle above the plant site and unobstructed view from Elephant Peak (KOP 11). Although Elephant Peak is 1 mile from the plant site, it receives very low visitor use due to its remote location and non-motorized accessibility. Because the plant site and adit entrances would be between two vegetated ridges to the north and south, views from the roads would be very short duration and partially obscured by vegetation; views from the CMW would be partially or entirely obstructed by topography and vegetation.

Landscape character would be changed over the short term due to the construction of the plant facilities, specifically to the vegetation pattern and land use. These changes would alter scenic integrity by introducing noticeable contrasts. The visual absorption capability of the plant site is high, indicating a substantial capacity to accommodate change, and the area of disturbance would be relatively small in most views.

Following the mine closure, regrading and revegetation would create areas with similar landscape characteristics to the existing timber harvested areas. In Alternative 2, the KFP would be amended to change those areas in a current Management Area with a VQO of Retention at the Plant Site to an MA with a VQO of Maximum Modification. The entire plant site would meet all Maximum Modification VQO criteria during construction, operations, and post-closure.

3.17.4.2.3 LAD Areas

Use of the two LAD Areas would alter the scenic integrity over the short term from the representative viewpoint along NFS road #4776C at KOP 2, the scenic overlook at KOP 3, a portion of NFS roads #231 and #4776, and portions of the CMW (Figure 82). Viewing significance from the two KOPs and two roads is high due to high visitor use and/or close proximity to the LAD Areas. Views from the KOPs are also long duration, while views from the two roads are short duration and partially obscured by vegetation. Viewing significance from the private land parcel east and south of the LAD Areas would be high due to potential long duration viewing times and close viewer proximity to the LAD Areas. The private land parcel north of Bear Creek would not be affected due to the screening effects of trees and topography.

The visible landscape character, such as the landform, vegetation pattern, and land use, would be changed over the short term due to the use of the LAD Areas. These changes would alter scenic integrity by introducing noticeable and substantial contrasts. The visual absorption capability of the LAD Areas is high, indicating a substantial capacity to accommodate change. For example, tree clearings would have some similar landscape characteristics to the tree harvested areas in the same vicinity as the LAD Areas. Following the mine closure, regrading and revegetation of the LAD Areas would potentially create areas with landscape characteristics identical to the existing timber harvested areas.

The KFP in this alternative would be amended to change the current MA with a VQO of Partial Retention at the LAD Areas to an MA with a VQO of Maximum Modification. The LAD Areas would meet all Maximum Modification VQO criteria during construction, operations, and post-closure.

3.17.4.2.4 Little Cherry Creek Tailings Impoundment Site

The Little Cherry Creek Tailings Impoundment Site would alter scenic integrity from KOPs 1, 2, and 3, a portion of NFS roads #231 and #4776, and portions of the CMW. Viewing significance from the three KOPs and two roads is high due to high visitor use, close proximity to the impoundment, long viewing duration, and a high viewing angle above the impoundment site. From KOP 2, the scenic overlook, about one-fourth of the impoundment site would be obstructed from view due to the screening effects of topography and vegetation. Although the visual absorption capability of the tailings impoundment location is moderate, its relatively large size in all views would create noticeable contrasts in landscape character and substantial alterations in scenic integrity. A visual simulation of the Little Cherry Creek Tailings Impoundment Site from KOP 2, a representative view from NFS road #4776C, is presented in Appendix I.

KOPs 1, 2, and 3, would have a mostly unobscured direct line of sight and view of a majority of the tailings impoundment. Because each KOP is a destination for scenic viewing, these views are also long in duration. KOPs 1 and 2 receive high visitor use. These two points are easily accessed by all vehicle types and are located relatively close to Libby and US 2. Local residents often bring out-of-town visitors to these KOPs for scenic viewing.

Views of the tailings impoundment from NFS roads #231 and #4776 would be partially obscured by vegetation. Openings in the vegetation also would frame, and emphasize views of the tailings impoundment. Although these views would be mostly from slow-moving vehicles with short-viewing durations, the tailings impoundment would be visible from about 2 miles of NFS road #231, and about 1 mile of NFS road #4776. From NFS road #231 views of the tailings impoundment would be mostly perpendicular to the direction of travel, and from NFS road #4776 views would be directly in line with the direction of travel to the northwest. These two roads are the main vehicular access to KOPs 1 and 2.

Above timberline, dispersed recreational users in some areas of the CMW, would have unobstructed views of the entire tailings impoundment. Views from the CMW below timberline would be similar, but would be partially obscured by vegetation. The landform contrast and relatively large size of the tailings impoundment would create a noticeable interruption of scenic integrity from KOP 3, Elephant Peak, most locations in the CMW east of the major peaks ridgeline, and up to 6 miles away.

Scenic integrity and landscape character from the private land parcel southeast of the impoundment dam, about 0.5 mile (2,700 feet) between dam and nearest property line, would be permanently altered. Scenic integrity would be reduced in northwesterly views from the north end of the private parcel due to a view of the impoundment dam face partially obscured by trees and topography. Scenic integrity would be minimally reduced in northwesterly views from the southern portion of private land due to the increasing screening effects of the forest with increasing distance from the impoundment. The perceived size of the impoundment also would diminish with increasing viewing distance.

Scenic integrity and landscape character from the private land parcel north of the impoundment site, about 0.25 mile (1,400 feet) between impoundment site and nearest property line, would not be affected, or affected only nominally. Visibility of the impoundment site, in southerly views only, would be mostly, or completely, obscured by topography and trees.

The visual absorption capability of the tailings impoundment location and surrounding vicinity is moderate, indicating a moderate capacity to accommodate noticeable change. Disturbances of landform, major disruptions of vegetation patterns, or substantial changes in land use at the impoundment site would be highly noticeable. The line, color, texture, and form of the existing forest vegetation and topography would be in high contrast with the adjacent unaffected vegetation and landforms. Following the mine closure, revegetation of the tailings impoundment would restore some color and texture characteristics similar to the adjacent undisturbed vegetation. Because of the large size and contrasting form, the tailings impoundment would remain an interruption of the scenic integrity of the site. Following mine closure, revegetation of the tailings impoundment would partially reduce color and texture contrasts between the tailings impoundment and surrounding landscape.

The KFP in this alternative would be amended to change those areas in MAs with VQOs of Partial Retention or Modification at the impoundment area to an MA with a VQO of Maximum Modification. The entire tailings impoundment would meet all Maximum Modification VQO criteria during construction, operations, and post-closure.

3.17.4.2.5 Change in VQO

As discussed in previous sections, the KFP in all mine alternatives would be amended to change the current MAs with varying VQOs of the plant site, LAD Areas, and tailings impoundment to an MA with a VQO of Maximum Modification. The change in VQO in the combined mine and transmission line alternatives is shown in Table 150.

None of the alternatives would change the extent of Preservation VQO. Alternative 2 would reduce Retention, Partial Retention, and Modification VQOs and increase Maximum Modification VQO.

Table 150. Change in VQO in the Analysis Area by Combined Mine-Transmission Line Alternative.

VQO	Alternative 1 No Action	Alternative 2 MMC's Proposed Mine	Alternative 3 Agency Mitigated Poorman Impoundment Alternative			Alternative 4 Agency Mitigated Little Cherry Creek Impoundment Alternative		
		TL-B	TL-C	TL-D	TL-E	TL-C	TL-D	TL-E
Preservation	66	66 (0)	66 (0)	66 (0)	66 (0)	66 (0)	66 (0)	66 (0)
Retention	2,402	2,245 (-157)	2,517 (+115)	2,517 (+115)	2,517 (+115)	2,517 (+115)	2,517 (+115)	2,517 (+115)
Partial Retention	4,180	3,773 (-407)	3,961 (-219)	3,960 (-220)	3,965 (-215)	3,849 (-331)	3,849 (-331)	3,853 (-327)
Modification	15,190	13,767 (-1,422)	14,552 (-638)	14,604 (-586)	14,388 (-802)	14,275 (-915)	14,327 (-863)	14,111 (-1,079)
Maximum Modification	3,727	5,714 (+1,987)	4,469 (+742)	4,418 (+691)	4,629 (+902)	4,858 (+1,131)	4,806 (+1,079)	5,018 (+1,291)

Number in parentheses is the reduction in acres of each VQO due to the alternative compared to Alternative 1, No Mine/No Transmission Line.
Source: GIS analysis by ERO Resources Corp. using KNF data.

3.17.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

In the agencies' mine and transmission line alternatives, MMC would implement a number of measures to harmonize operations with scenic values. MMC would complete vegetation clearing operations and painting of structures under the supervision of an agency representative with experience in landscape architecture and revegetation. Where practicable, MMC would create clearing edges with shapes directly related to topography, existing vegetation community densities and ages, surface drainage patterns, existing forest species diversity, and view characteristics from KOPs. MMC would avoid straight line or right-angle clearing area edges. MMC would paint structures to blend in with the surrounding landscape. MMC would not create symmetrically-shaped clearing areas.

MMC would transition forested clearing area edges into existing treeless areas by varying the density of the cleared edge under the supervision of an agency representative. MMC would mark only trees to be removed with water-based paint, and not mark any trees to remain. MMC would cut all tree trunks at 6 inches or less above the existing grade in clearing areas located in sensitive foreground areas such as within 1,000 feet of residences, roads, and recreation areas. These locations would be determined and identified by an agency representative before clearing operations.

3.17.4.3.1 Libby Creek and Rock Lake Adits

Effects on scenery at the Libby Adit Site would be slightly greater than Alternative 2 because of a larger area of contrasts created by the Upper Libby Adit and additional area of disturbance. Although the disturbed area would remain relatively small in the views from KOPs 2 and 3, the roads, and the CMW, the larger size of the contrasts would create a slightly greater visual distraction. Effects on scenic integrity and landscape character due to the Rock Lake Ventilation

Adit, located on MMC private land, would be the same as Alternative 2. MMC would, where possible, screen the Rock Lake Ventilation Adit from view using native materials.

3.17.4.3.2 Libby Plant Site

Construction and use of the Libby Plant Site would alter the scenic integrity from KOPs 2, 3, and 4, a portion of NFS roads #231 and #4776C, portions of the CMW, and the private land parcel east of the plant site (Figure 82). The plant site would be located on a ridge between the Libby and Ramsey Creek valleys and would be highly visible. Viewing significance from KOP 2 is high due to high visitor use along NFS road #4776C, the high view angle above the plant site, and an unobstructed view of the entire plant site. Views from KOP 3 and Elephant Peak would have similar characteristics. Views from NFS roads #231 and #4776C would be short duration and partially obscured by vegetation. Views from CMW in the forest also would be partially obstructed by vegetation. Views from CMW above timberline would be completely unobstructed. Only a relatively small portion of the plant site would be visible from the private land parcel due to the screening effects of trees and topography.

The landscape character would change due to the construction of the plant facilities, specifically to the vegetation pattern, landform, and land use. These changes would alter scenic integrity by introducing noticeable contrasts. The visual absorption capability of the plant site is low, indicating a small capacity to accommodate change. Following the mine closure, regrading and revegetation would potentially create areas with similar landscape characteristics to the existing timber harvested areas. The KFP amendment in this alternative would change the current MA with a VQO of Modification to an MA with a VQO of Maximum Modification. The plant site would meet all Maximum Modification VQO criteria during construction, operations, and post-closure.

3.17.4.3.3 Poorman Tailings Impoundment Site

Effects on scenic integrity and landscape character due to the Poorman Tailings Impoundment Site would be similar to the Little Cherry Creek Tailings Impoundment Site in Alternatives 2 and 4. Because of the impoundment's location, the entire impoundment site would be visible from the scenic overlook at KOP 3. All other scenic integrity, landscape character, and visual absorption capability characteristics would be the same as Alternatives 2 and 4. The tailings impoundment site would meet all applicable Maximum Modification VQO criteria. A visual simulation of the Poorman Tailings Impoundment Site from KOP 2 is presented in Appendix I.

Scenic integrity and landscape character from the private land parcel due east of the impoundment dam, about 0.06 miles (350 feet) between dam and nearest property line, would be permanently and substantially altered. Scenic integrity would be substantially reduced in westerly views from the north end of the private parcel due to a mostly unobstructed view of the 270-foot high impoundment dam face. Scenic integrity would be moderately reduced in northwesterly views from the southern portion of this parcel due to the increasing screening effects of the forest with increasing distance from the impoundment. The size of the impoundment also would be diminishing with increasing viewing distance.

Scenic integrity and landscape character from the private land parcel north of the impoundment site, about 1.1 miles (5,700 feet) between impoundment site and nearest property line, would not be affected, or affected only nominally. Visibility of the impoundment site in southerly views only, would be mostly, or completely, obscured by topography and trees. Following mine closure, revegetation of the tailings impoundment would partially reduce color and texture contrasts between the tailings impoundment and surrounding landscape.

The KFP in this alternative would be amended to change those areas in current MAs with VQOs of Partial Retention or Modification at the impoundment area to an MA with a VQO of Maximum Modification. The tailings impoundment would meet all Maximum Modification VQO criteria during construction, operations, and post-closure.

3.17.4.3.4 Change in VQO

Alternative 3, in combination with the transmission line alternatives, would reduce Partial Retention and Modification VQOs and increase Retention and Maximum Modification VQOs (Table 150).

3.17.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Effects on scenic integrity and landscape character due to the Libby Plant Site, Libby Adit Site, upper Libby Adit Site, and Rock Lake Ventilation Adit would be the same as for Alternative 3. Effects on scenic integrity and landscape character due to the Little Cherry Creek Tailings Impoundment Site would be the same as for Alternative 2.

Alternative 4, in combination would all transmission line alternatives would reduce Partial Retention and Modification VQOs and increase Retention and Maximum Modification VQOs (Table 150). The reduction in Partial Retention and Modification would be less than Alternative 2 and more than Alternative 3.

3.17.4.5 Alternative A – No Transmission Line

The analysis area's existing scenic integrity and landscape character as viewed from KOPs would not change in Alternative A. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. The visual effect of the Libby Adit would remain until it was reclaimed in accordance with existing permits and approvals.

3.17.4.6 Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

The segments of the North Miller Creek Alternative visible from the viewing locations, KOPs, high use roads, and the CMW, are shown on Figure 82. This alternative would be visible from the most KOPs. About 6.4 miles of transmission line would be visible from five of the 11 KOPs, 3, 8, 9, 10, and 11 (Table 151). KOPs 8, 9, and 11 are located on private land. Visibility of the transmission line, structures, and tree clearing area would be very low and partially obscured from KOPs 8 and 9 due to the screening effects of topographic changes and trees. Effects on KOPs would be negligible because a relatively small portion of the tops of the transmission line structures would be visible above evergreen treetops, and the visible tops would be a very small size within the views. Additionally, the tops of the structures would be relatively small portions of views from the KOPs. This alternative would have visibility of the transmission line from the most acres of CMW and second least miles from high use roads (Table 152). The length of high

Table 151. Transmission Line Length Visible from KOPs.

KOP	Alternative B – North Miller Creek	Alternative C-R – Modified North Miller Creek	Alternative D-R – Miller Creek	Alternative E-R – West Fisher Creek

Table 152. Visibility of Transmission Line from KOPs, Roads, and the CMW.

Location	Alternative B – North Miller Creek	Alternative C-R – Modified North Miller Creek	Alternative D-R – Miller Creek	Alternative E-R – West Fisher Creek
KOPs (number)	5	3	3	3
High use roads (miles)	11.19	9.89	11.92	11.99
CMW (acres)	1,630	1,480	1,450	1,470

KOP = key observation point.
CMW = Cabinet Mountains Wilderness.
Source: GIS analysis by ERO Resources Corp. using KNF data.

use roads with transmission line visibility would be the same as Alternative D-R. The KFP in this alternative would be amended to change those areas in an MA with VQOs of Retention or Partial Retention to an MA with a VQO of Maximum Modification. This alternative would meet all Modification and Maximum Modification VQO criteria.

BPA's Sedlak Park Substation and loop line would be on private land owned by Plum Creek. It is not be subject to Forest Service visual management standards. The substation's perimeter would be illuminated during nighttime hours, and lighting would be directed downward to mitigate light and glare. One residence would have a direct view of the proposed substation location.

3.17.4.7 Alternative C-R – Modified North Miller Creek Transmission Line Alternative

The agencies' transmission line alternatives incorporated several mitigations to avoid or minimize effects on visual resources. All agency alternatives use an alignment that route the line on an east-facing ridge immediately north of the Sedlak Park Substation instead of following the Fisher River, reducing visibility from US 2. All agency alternatives also would use wooden H-frame structures, which are shorter and would be less visible. During final design, MMC would submit a final Vegetation Removal and Disposition Plan for lead agencies' approval. The plan's goal would be to minimize vegetation clearing, particularly in riparian areas. The agencies modified MMC's proposed Environmental Specifications to incorporate current transmission line construction practices. The agencies' Environmental Specifications, shown in Appendix D, would be implemented to guide line construction, operation, maintenance, and decommissioning activities in all of the agencies' transmission line alternatives. The agencies' Environmental Specifications also include sensitive areas, such as high visibility areas, where special measures would be taken to reduce impacts during construction and reclamation activities. In all of the agencies' transmission line alternatives, MMC would implement the measures to harmonize operations with scenic values discussed under Alternative 3.

The segments of the Modified North Miller Creek Alternative visible from the viewing locations, KOPs, high use roads, and the CMW, are shown on Figure 82. About 0.9 miles of transmission line would be visible from three of the 11 KOPs (Table 151). Visibility of the transmission line, structures, and tree clearing area would be very low and partially obscured from KOPs 9 and 10 due to the screening effects of topographic changes and trees. Effects on KOP 3 would be the same as for Alternative B.

This alternative would have visibility of the transmission line from the second most acres of CMW, and least miles from high use roads (Table 152). The KFP in this alternative would be amended to change those areas in an MA with VQOs of Retention or Partial Retention to an MA with a VQO of Maximum Modification. This alternative would meet all Modification and Maximum Modification VQO criteria. The visual effect of BPA's Sedlak Park Substation would be the same as Alternative B.

3.17.4.8 Alternative D-R – Miller Creek Transmission Line Alternative

The segments of the Miller Creek Alternative visible from the viewing locations, KOPs, high use roads, and the CMW, are shown on Figure 82. About 0.8 mile of transmission line would be visible from three of the 11 KOPs (Table 151). Visibility of the transmission line, structures, and tree clearing area would be very low and partially obscured from KOPs 9 and 10 due to the screening effects of topographic changes and trees. Effects on KOP 5, at Howard Lake, would be high visibility, high contrast, and noticeable change to the existing line, color, and texture of the forest. Most visitors to Howard Lake would have unobstructed views of a portion of this alternative. A photographic simulation of the view from the Howard Lake boat ramp with Alternative D-R is in Appendix I.

This alternative would have visibility of the transmission line from the least acres of CMW, and the second most miles from high use roads (Table 152). The KFP in this alternative would be amended to change those areas in an MA with VQOs of Retention or Partial Retention to an MA with a VQO of Maximum Modification. This alternative would meet all Modification and

Maximum Modification VQO criteria. The visual effect of BPA's Sedlak Park Substation would be the same as Alternative B.

3.17.4.9 Alternative E-R – West Fisher Creek Transmission Line Alternative

The segments of the West Fisher Alternative visible from the viewing locations, KOPs, high use roads, and the CMW, are shown on Figure 82. About 0.6 mile of transmission line would be visible from three of the 11 KOPs (Table 151). Effects from KOPs 5, 9, and 10 would be the same as Alternative D-R.

This alternative would have visibility of the transmission line from the second least acres of CMW, and most miles from high use roads (Table 152). The KFP in this alternative would be amended to change those areas in an MA with VQOs of Retention or Partial to an MA with a VQO of Maximum Modification. This alternative would meet all Modification and Maximum Modification VQO criteria. The visual effect of BPA's Sedlak Park Substation would be the same as Alternative B.

Based on all KOP, road, and CMW locations with transmission line visibility, Alternative B would have the greatest length of high transmission line visibility at 3.8 miles. Alternative D-R would have the greatest length of transmission line with no visibility of 1.5 miles (Table 153).

Table 153. Visibility Levels of Transmission Line Alternatives.

Visibility	Alternative B – North Miller Creek	Alternative C-R – Modified North Miller Creek	Alternative D-R – Miller Creek	Alternative E-R – West Fisher Creek
No Visibility	2.1	2.5	1.5	1.7
Low	2.5	2.8	4.1	2.8
Moderate	8.0	5.8	6.6	8.1
High	3.8	2.1	1.6	2.7

All units are in miles.

3.17.4.10 Effectiveness of Agencies' Proposed Mitigation

In Alternatives 3 and 4, MMC would regrade and shape flat surfaces to blend with the adjacent landscape and have natural dendritic drainages. Additional fill would be used as necessary to create smooth transitions between human-made and natural landforms whenever project facilities were reclaimed. MMC also would develop a design to recontour faces of the tailings impoundment dams to more closely blend with the surrounding landscape than proposed in Alternative 2. Although reclaimed areas would generally have noticeably different lines, colors, and textures, the mitigation measures included in the reclamation process in Alternatives 3 and 4 would reduce or eliminate some of these contrasts. For example, the visible effects of vegetation color contrasts would no longer be apparent sometime after reclamation. At the proposed tailings impoundment location, mitigation measures would reduce but not eliminate the effects of the line, color, and texture contrasts. The proposed tailings impoundment site would always have noticeable contrasts to the surrounding forest and landforms.

The effectiveness of other mitigation measures would include:

- Lighted mine facilities and roads used for mining operations would remain highly visible at night. Although shields or baffles at the light sources would prevent most glare from the bulb, the ambient light would be highly visible because the facility locations and roads are mostly dark, except at the Libby Adit.
- Grading to minimize disturbance area for mine facilities would reduce, but not eliminate visible contrasts with the surrounding landforms.
- Following mining operations, placement of waste rock underground in existing disturbed areas, or into the tailings impoundment would eliminate the visible contrasts of color and texture, and minimize areas of disturbance.
- Completing the vegetation clearing operation under the supervision of an agency representative would minimize the areas of disturbance and therefore minimize the visibility of mine facilities and the transmission line. Creating clearing edges with varying shapes responding to the composition of the adjacent forest, existing topography, and views from KOPs would reduce, and possibly eliminate visibility of some mine facilities and the transmission line from some KOPs, and minimize the contrasts of line. Varying the density of the clearing edges would also minimize the visibility of the edges.
- Marking trees for removal as opposed for preservation would not leave paint markings on trees remaining in the vicinity of the proposed facilities and along the transmission line clearing corridor.
- Cutting all trees in clearing areas to within 6” of the ground and within 1,000’ of KOPs, would reduce, but not eliminate, the visible presence of cut tree trunks, and the contrasts of color and texture.
- Locating mine facilities and the transmission line below the horizon line as viewed from the KOPs reduces, but does not eliminate, visibility and the contrasts of line, color, and texture of the facilities and transmission line.

During operations, mitigation measures of the transmission line alternatives would also reduce the noticeable contrasts created by the presence of the line, structures, new roads, and tree clearing corridors. These facilities would remain visible throughout operations. Although the use of wood poles, non-specular conductors, and non-reflective insulators would reduce the contrasts of texture with the surrounding forest and the reflection of light, these facilities would remain visible. Variations in the width and shape of the forest clearing corridors would create some forest edge characteristics edges similar to naturally-formed clearings. Leaving a variety of species and tree sizes at the clearing edges would also create the appearance of naturally-formed clearing edges. Clearing corridors would remain highly visible and in contrast with the surrounding forest. Following the mine closure and reclamation, the visible effects of the transmission line would be eliminated when tree height and density matched the surrounding forest.

During operations, mitigation measures of the mine facilities’ night lighting would reduce the amount of visible artificial light. Although light fixture baffles and directional light sources diminish the amount of ambient light emanating from a fixture, some ambient light would remain, and the light source would remain visible from some locations.

3.17.4.11 Cumulative Effects

Past actions of timber harvest and road construction have altered the scenic integrity of characteristic landscapes of the analysis area. Roads have created linear features visible throughout the analysis area. Timber harvests have altered the line, color, and texture of the undisturbed landscape. The future construction and operation activities of the Poker Hill Rock Quarry near NFS road #231 would affect the scenic integrity of views from the road. Both the quarry and planned mine facilities would be visible from NFS road #231. Timber harvest associated with the Miller-West Fisher Vegetation Management Project also would affect views from NFS roads #231 and #385. Cumulative visual impacts would occur for wilderness hikers visiting Ojibway Peak where views extend toward both the East Fork Rock Creek west of the Cabinet Mountains and Libby Creek east of the Cabinet Mountains. From a small area on the peak, both the preferred mill site for the Rock Creek Project and the Libby Plant Site and Libby Adit for the Montanore Project would be visible. Indirect impacts may occur for CMW visitors to other wilderness peaks, as either project may be visible from some wilderness viewpoints.

3.17.4.12 Regulatory/Forest Plan Consistency

3.17.4.12.1 Organic Administration Act and Forest Service Locatable Minerals Regulations

The Forest Service is responsible for ensuring that mine operations on National Forest System lands comply with Forest Service locatable mineral regulations (36 CFR 228 Subpart A) for environmental protection. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources. 36 CFR 228.8(d) also requires that mining operators, to the extent practicable, harmonize operations with scenic values through such measures as the design and location of operating facilities, including roads and other means of access, vegetative screening of operations, and construction of structures and improvements which blend with the landscape.

Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8(d). In this alternative, MMC did not propose to implement practicable measures to harmonize operations with scenic values.

The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) were developed and incorporated feasible and practicable measures to minimize adverse environmental impacts and harmonize operations with scenic values. Transmission Line Alternatives C-R, D-R, and E-R were developed and revised to address visual issues. The alignment of the line was moved away from private property and located away from the Hwy 2 corridor to reduce visual impacts of the line. The structure type was modified from a monopole to a h frame to reduce visual impacts as well. Mitigation measures in Alternatives 3 and 4, would include regrading and shaping of flat surfaces to blend with the adjacent landscape and have natural dendritic drainages. Additional fill would be used as necessary to create smooth transitions between human-made and natural landforms. MMC also would develop a design to recontour faces of the tailings impoundment dams to more closely blend with the surrounding landscape than proposed in Alternative 2. Additional mitigation measures include baffling or shielding night light, painting of structures to blend in with surrounding landscape minimizing the visibility of the clearing edges. Measures are further described in the previous discussion on *Effectiveness of Agencies' Proposed Mitigation*.

3.17.4.12.2 Kootenai Forest Plan

All mine and transmission line alternatives would meet all VQO criteria for National Forest System lands following the KFP amendment in each agency alternative. There are no visual regulatory requirements for BPA's Sedlak Park Substation and loop line situated on private land.

3.17.4.13 Irreversible and Irretrievable Commitments

Landform changes caused by the tailings impoundments would alter the scenery and would be an irreversible commitment of visual resources. Changes in scenery from other mine facilities would be an irretrievable commitment of resources. At the mine closure, disturbed areas would be regraded and revegetated, and all buildings and other constructed facilities would be removed. Reclaimed areas would have noticeably different lines, colors, and textures than the adjacent undisturbed landscape.

3.17.4.14 Short-term Uses and Long-term Productivity

Short-term uses affecting scenery would include construction of all proposed mine facilities and the transmission line. In addition, there would be the short-term effects from the presence of fugitive dust from construction activities, night lighting for construction operations, and vehicle traffic.

Long-term effects on scenery would be loss of vegetation and landform changes at all mine facilities and along the transmission line during the life of the mine. Following mine closure, landscape reclamation at all mine facilities, except the tailings impoundment, would create areas similar in appearance to abandoned roads and timber harvest areas. The tailings impoundment would have physical characteristics in substantial contrast to the surrounding landscape. The scenic integrity and landscape character changes at the impoundment site would be noticeable indefinitely.

3.17.4.15 Unavoidable Adverse Environmental Effects

Visual impacts of all action alternatives would be unavoidable. Existing settings and landscapes in the analysis would be altered during mine operation and for several decades following operations.

3.18 Social/Economics

3.18.1 Regulatory Framework

3.18.1.1 Forest Plan

The KFP guides all natural resource management activities and establishes management standards for the KNF (USDA Forest Service 1987a). The KFP establishes management direction in the form of prescriptions consisting of goals, objectives, standards, and guidelines. Goals provide information on the long-range management intent. The objectives and standards of both the forest as a whole and individual MAs must support the goals. MA designations, goals, and standards are described in detail in section 3.15.3.2.2*, Management Area Goals and Standards*. All activities conducted on the KNF must contribute to the realization of the goals. The goal for mineral development is to "encourage responsible development of mineral resources in a manner that recognizes national and local needs and provides for economically and environmentally sound exploration, extraction, and reclamation." The KFP also establishes a goal of providing a sustained yield of timber volume responsive to market demands and supportive of a stable base of economic growth in the dependent geographic area. Management direction for the analysis area is described in more detail in section 3.15.3.2*, Kootenai National Forest Land Management Plan.*

3.18.1.2 Hard Rock Mining Impact Act

The Hard Rock Mining Impact Act is designed to assist local governments in handling financial impacts caused by large-scale mineral development projects. A new mineral development may result in the need for local governments to provide additional services and facilities before mine-related revenues become available. The resulting costs can create a fiscal burden for local taxpayers. The Hard Rock Mining Impact Board (HRMIB) oversees an established process for identifying and mitigating fiscal impacts on local governments through the development of a Hard Rock Mining Impact Plan. Under the Impact Act, each new large-scale hard-rock mineral development in Montana is required to prepare a local government fiscal Impact Plan. In the plan, the developer is to identify and commit to pay all increased capital and net operating costs to local government units that will result from the mineral development.

MMC updated the Impact Plan with the cooperation of the affected local governments (Western Economic Services, LLC 2005) and submitted it to Lincoln County for its review. Lincoln County approved the updated plan in 2007. Because the Montanore Project as currently proposed would change employment projections, MMC submitted an amendment for consideration by the HRMIB. The HRMIB approved the amendment in 2008.

3.18.1.3 Major Facility Siting Act

The purposes of the MFSA for the construction of electric transmission lines are to: ensure the protection of the state's environmental resources; ensure the consideration of socioeconomic impacts; provide citizens with an opportunity to participate in facility siting decisions; and establish a coordinated and efficient method for the processing of all authorizations required for regulated facilities. The MFSA directs the DEQ to approve a facility if, in conjunction with other findings, the DEQ finds and determines that the facility would minimize adverse environmental impacts considering the state of available technology and the nature and economics of the various alternatives.

3.18.2 Analysis Area and Methods

The socioeconomic analysis area is based on various factors that may influence the location and magnitude of potential socioeconomic impacts. Some of these factors include:

- The location of and access to the ore body and to the proposed permit area
- The likely residence area for people working at the mine (existing residents and/or any in-migrating project employees)
- The rate and magnitude of in-migration (which will be influenced by the availability of a trained or trainable local workforce and a developer-sponsored training program)
- The rate and magnitude of population and employee turnover (including student population turnover in schools, employee turnover at the mine, and employee turnover from existing jobs to employment with the Montanore Project)
- The availability and location of existing housing and potential housing and the capacity and condition of existing local services and facilities
- The people directly/indirectly affected economically by the proposed mining operation (*e.g.*, from wages and taxes)
- The willingness and ability of community residents and local government personnel to deal with change
- The allocation and magnitude of costs associated with in-migration of workers and allocation of tax revenues
- Impacts on Sanders County from removing ore and processing in Lincoln County

Based on these factors, the socioeconomic analysis area for the proposed project is Lincoln County and the Towns of Libby, Troy, and Eureka. Affected jurisdictions in the analysis area include the incorporated municipalities of Libby and Troy as well as the Libby, Troy, and Eureka School Districts (Western Economic Services, LLC 2005).

Economic effects on Sanders County would result primarily from the distribution of metal mines tax revenues to Sanders County. Relevant baseline information in Sanders County is provided in section 3.18.3.7*, Fiscal Conditions* because socioeconomic effects are likely to be limited to direct payments to Sanders County that would be distributed among various county agencies. Other baseline data for Sanders County related to population, housing, income, employment, and quality of life are not provided for because in-migrating mineworkers are not expected to establish residency there, and effects on Sanders County would be negligible (Western Economic Services, LLC 2005). Unless otherwise specified, socioeconomic data contained in this section are based on information provided in the *2005 Socioeconomic Report for the Mines Management Montanore Project* (Western Economic Services, LLC 2006).

3.18.3 Affected Environment

3.18.3.1 Population and Demographics

3.18.3.1.1 Historical Population Trends and Characteristics

Since 1950, Lincoln County has experienced relatively substantial fluctuations in its population. Lincoln County experienced the largest increase in population (44 percent) between 1960 and 1970 due to construction of Libby Dam. Between 1970 and 1980, Lincoln County's population declined by about 1.7 percent. This decline is attributable to the out-migration of construction workers when Libby Dam was completed. The population recovered, by almost 8 percent, from 17,481 people in 1990 to 18,837 people in 2000 (Table 154). The U.S. Census Bureau's 2010 population estimate of 19,687 people in Lincoln County indicates that the population has grown by 4.5 percent since 2000 (U.S. Census Bureau 2012a).

Table 154. Lincoln County Population Characteristics (1970-2010).

Year	1970	1980	1990	2000	2010
Lincoln County	18,063	17,752	17,481	18,837	19,687
% Change		-1.7	-1.5	7.8	4.5
Libby	3,286	2,748	2,532	2,626	2,628
% Change		-16.4	-7.9	3.7	<0.1
Eureka	1,195	1,119	1,043	1,017	1,037
% Change		-6.4	-6.8	-2.5	2.0
Troy	1,046	1,088	953	957	938
% Change		4.0	-12.4	0.4	-2.0
Montana	694,409	786,690	799,065	902,125	989,415
% Change		13.3	1.6	12.9	9.7

Source: Western Economic Services, LLC 2006; U.S. Census Bureau 2012a.

In 2010, the median age for both males and females in Lincoln County was 49 years, compared to 40 years in the state. Lincoln County has experienced an increase in the number of older residents due in part to the popularity of second homes in rural mountain communities. From 2000 to 2010, people between the ages of 55 to 64 increased from 2,459 to 3,675 (49.5 percent) and people 65 or older increased from 2,859 to 4,040 (41.3 percent). For the state of Montana over the same period, the number of people between the ages 55 to 64 increased from 85,119 to 138,858 (63.1 percent), and the number of people 65 and older increased from 120,949 to 146,742 (21.3 percent).

3.18.3.1.2 Major Population Centers

Major population centers in Lincoln County include the towns of Libby, Troy, and Eureka. Libby is the largest town in Lincoln County, with about 23 percent of the population (Table 154). Each town's 2010 population was within 5 percent of 2000 populations. Population trends in Libby are similar to those described for the county. Libby has a higher percentage (22.5 percent) of its population over 65 years of age compared to Lincoln County (20.5 percent) and the state of Montana (14.8 percent) (U.S. Census Bureau 2012b).

3.18.3.1.3 Population Projections

Under current conditions, the Lincoln County population is projected to increase by 0.8 percent per year, rising from 19,687 people in 2010 to 22,740 people by 2030 (Table 155). Population projections for municipalities within Lincoln County were obtained by applying county population actual and projected growth rates from 1970 to 2030 to the municipalities. The population in Libby is expected to increase by 518 persons from 2,628 people in 2010 to 3,146 people in 2030. Eureka's population is expected to increase by 181 people and Troy's population is expected to increase by 225. Much of the projected population growth is attributed to expected increases in retirees and other older, affluent newcomers (Lincoln County 2009).

Table 155. Population Projections for Lincoln County and Municipalities (2010 – 2030).

Year	2010	2015	2020	2025	2030
Lincoln County	19,687	19,738	20,483	21,505	22,740
Libby	2,628	2,731	2,834	2,975	3,146
Eureka	1,037	1,057	1,097	1,152	1,218
Troy	938	1,009	1,047	1,100	1,163

Source: Western Economic Services, LLC 2006.

3.18.3.1.4 Minority Populations

Census data for Lincoln County are broken down within Census Tracts to show the distribution of minorities within the county. Libby is located almost entirely in Census Tract 2. Eureka is part of Census Tract 4 and Troy is part of Census Tract 5 (Table 156). In the 2010 Census, racial minorities represented 4.1 percent of the total County population. Another 2.3 percent of the County population falls under the category of individuals of two or more races.

Table 156. Population by Race and Ethnicity.

Race	Census Tract 1	Census Tract 2	Census Tract 3	Census Tract 4	Census Tract 5	Total	% Total Population
White	3,446	2,268	3,773	5,977	3,417	18,881	95.9
Black	6	3	3	7	4	23	0.1
American Indian or Alaskan Native	29	31	29	62	31	182	0.9
Asian	10	10	14	13	13	60	0.3
Native Hawaiian and Other Pacific Islander	4	1	1	1	2	9	0.0
Some Other Race	6	9	19	31	6	71	0.4
Two or More Races	88	57	83	130	103	461	2.3
Total	3,589	2,379	3,922	6,221	3,576	19,687	100.0
Hispanic	50	64	101	188	59	462	2.4

Source: U.S. Census Bureau 2012c.

3.18.3.1.5 Disabled Populations

Disability is categorized by the Census Bureau into communicative, physical, and mental domains. Broadly, disability is an umbrella term for impairments, activity limitations, and participation restrictions. In the 2000 Census, 4,012 people, or about 21.3 percent of the population in Lincoln County were classified as disabled; this compares to about 12.8 percent of the state population. The large numbered of disabled people can be attributed in part to former vermiculite mine workers from the W.R. Grace Mine who suffer from asbestos-related diseases. Specifically, for a 20-year period (1979 to 1998) examined, asbestosis mortality in Libby was 40 to 80 times higher than expected and lung cancer mortality was 1.2 to 1.3 times higher than expected when compared to Montana and the United States (Agency for Toxic Substances and Disease Registry 2002).

3.18.3.2 Employment

Employment conditions for Lincoln County are presented in terms of historical employment trends, current types of employment, and baseline (i.e., with no mine) employment projections. Lincoln County's economy has typically centered on natural resource extraction industries such as mining and logging. Mining has historically been a dominant feature of the Lincoln County economy. The Rainey Creek and Fisher River Districts, east of Libby, and the Sylvanite and Keystone Districts, north of Troy, were productive mining areas before the 1940s. Gold, silver, copper, zinc, and lead were extracted from mines throughout Lincoln County. Until 1990, when the W.R. Grace mine was closed, Lincoln County was also the world's largest producer of vermiculite. Mining sector businesses represented 0.6 percent of all businesses, but about 7.0 percent of all County employment in 1986. In 2010, mining sector businesses represented 1.1 percent of all businesses and accounted for 4.6 percent of all County employment (Montana Department of Labor and Industry 2012a).

According to the Montana Department of Labor and Industry, lumber and wood products represented 42.1 percent (16 of 38) of all manufacturing establishments and 89.7 percent (651 of 726) of all manufacturing employment in 2000 in Lincoln County when Owens & Hurst Lumber, Plum Creek Lumber, and Stimson Lumber Company were the three largest lumber and wood product employers. During 2010, the latest data available, the lumber and wood products industry represented 27.6 percent (8 of 29) of all manufacturing establishments, and employment had declined to 24.1 percent (48 of 199) of manufacturing employment in Lincoln County. The strength of the lumber and wood products industry in Lincoln County has historically been tied to the strength of the national housing and construction market, as well as the local availability of timber. Between 1993 and 2005, five lumber mills closed, leaving only Plum Creek with continuing operations in Lincoln County.

In 2010, the top three employment sectors in Lincoln County were government and government enterprises, retail trade, and construction. The government and government enterprises sector, with 15 percent of total employment, was the largest sector in Lincoln County. The retail trade sector was the next largest with 11.9 percent of total employment followed by the construction sector with 8.6 percent of total employment (Table 157). Contributing to many sectors is a vibrant recreation industry that provides visitors numerous camping, hiking, skiing, snowmobiling, hunting and fishing, wildlife viewing, and other recreation opportunities.

The top 9 private employers for Lincoln County during the second quarter of 2011, listed in alphabetical order, were A Full LiveLife Agency, Genesis Inc., Harlow's School Bus Service, Libby Care Center, Mountain View Manor, Rosauer's Food and Drug, St John's Lutheran Hospital, Stein's IGA, and Town Pump (Montana Department of Labor and Industry 2012a).

Table 157. Lincoln County Employment Trends (2008 - 2010) for Major Industrial Sectors.

Industrial Sector	2008		2009		2010	
	Persons	%	Persons	%	Persons	%
Forestry, Fishing, and Related Activities	496	5.2	388	4.2	388	4.2
Mining	282	3.0	249	2.7	273	3.0
Construction	946	9.9	853	9.2	788	8.6
Manufacturing	413	4.3	359	3.9	353	3.8
Retail Trade	1,123	11.8	1,114	12.1	1,088	11.9
Government and Government Enterprises	1,354	14.2	1,382	15.0	1,373	15.0
Total Employment	9,537		9,241		9,176	

Employment based on the number of full- and part-time jobs.
Source: U.S. Bureau of Economic Analysis 2012a.

The labor force in Lincoln County, defined as persons working or seeking work, increased by 287 persons, from 7,623 in 2005 to 7,910 in 2010. This is an increase of 3.8 percent compared to an increase of 3.5 percent statewide over the same period. In Lincoln County, the average annual unemployment rate, the number of unemployed persons as a percentage of the labor force, increased from 7.4 percent in 2005 to 15.6 percent in 2010 (Montana Department of Labor and Industry 2012a). This was about twice the average annual unemployment rate of Montana, which was 7.2 percent during 2010 (Montana Department of Labor and Industry. 2012b).

Total employment in Lincoln County is projected to increase to 12,572 people by 2030. This increase represents an average annual growth rate of 1.3 percent between 2003 and 2030, higher than the historical 1970-2002 growth rate of 0.5 percent (Western Economic Services, LLC 2006).

3.18.3.3 Income

The 2010 median family income in 2010 in Lincoln County was $39,600, about 28.9 percent lower than the state-wide median family income of $55,725. Lincoln County’s per capita personal income, adjusted for inflation, was $28,404 in 2010, compared to $36,159 in Montana. This represents an increase of 37.5 percent since 1969 compared to an increase of 79.1 percent statewide over the same period (U.S. Bureau of Economic Analysis 2012b). Lincoln County’s average wage of $31,213 per year in 2010 was lower than the statewide average of $34,610 per year. The top-paying sectors of the economy included mining ($62,571 per year), government ($42,928 per year), and forestry and logging ($42,318 per year).

Between 2006 and 2010, Lincoln County had a greater percent (38.4 percent) of households earning less than $25,000 a year than in the state of Montana (27.5 percent). A total of 3,548 households in Lincoln County had incomes of less than $25,000. Census Tract 4, in which Eureka is located, had the highest concentration in the county, with 27.8 percent of households with incomes of less than $25,000 (U.S. Census Bureau 2012a).

3.18.3.4 Economic Activities that Rely on Natural Resources

The following sections briefly describe economic activities in the study area that rely on natural resources such as recreation, logging, mineral exploration, and agriculture. The *Logging*, *Mineral Exploration*, and *Agriculture* sections only discuss relevant activities near the analysis area, and are not designed to discuss all of Lincoln County. Additional information on these activities is discussed in sections 3.15, *Land Use* and 3.16, *Recreation.*

3.18.3.4.1 Recreation

National Forest System lands make up a large percentage of the Lincoln County land base and offer public access for a variety of motorized and non-motorized recreational activities including: hunting for big game and upland and migratory game birds, fishing, hiking, wildlife observation, berry picking, photography, backpacking, horseback riding, snowmobiling, mountain biking, picnicking, sightseeing, OHV use, amateur geology, and camping. Visitation estimates for 2007 on the KNF were 892,000 ± 18.9 percent. Greater than 72 percent of these visits were from people who lived within 100 miles of the KNF (USDA Forest Service 2011d).

Most of the visits to the KNF are day visits. The average visit to the KNF lasts about 10 hours; more than half of the visits to the KNF last less than five hours. Less than 10 percent of the visits involve recreating at more than one location on the KNF. Because of the local nature of the visiting population, frequent visitors are quite common. More than 38 percent of all visits are made by people who visit more than 50 times per year. Conversely, only about 25 percent of the visits are made by people who visit, at most, five times per year (USDA Forest Service 2011d).

3.18.3.4.2 Logging

The National Forest System lands of the Libby Ranger District provide about 6 to 8 million board feet (mmbf) of timber annually. No KNF timber sales are currently under contract in the land use analysis area as of 2012. As discussed in section 3.3, *Reasonable Foreseeable Future Actions or Conditions*, the KNF completed an EIS on the Miller-West Fisher Vegetation Management Project in the land use analysis area. Timber harvest activity also occurs on private, forest-industry lands. The amount of timber harvested has declined in the past 10 years. Small-scale timber harvests occur in the range of 2 to 6 mmbf annually on the private lands in the land use analysis area. Logging has taken place along Libby Creek on public lands since the late 1960s. Timber was harvested from upper Libby Creek and Ramsey Creek following the Libby Creek Road extension in the mid-1970s, resulting in a number of clear-cut areas within the analysis area. Plum Creek has harvested several tracts of private land on lower Miller Creek and along the Fisher River (Power Engineers, Inc. 2005c).

3.18.3.4.3 Mineral Exploration

Some mineral activity occurs near the proposed mine. This activity includes small placer operations on Libby and Big Cherry creeks, small lode mining operations along Libby Creek, Snowshoe Creek, at the headwaters of the West Fisher Creek, and in the Prospect Hill area, four miles south of Libby. A number of mineral operators do some form of work along the east face of the Cabinet Mountains each year (Power Engineers, Inc. 2005c).

3.18.3.4.4 Agriculture

No prime and unique farmland was identified near the proposed mining facilities; some land along US 2 is used for hay and grazing. In addition, no land is enrolled in the Conservation Reserve Program, and no grazing allotments are present on nearby National Forest System lands

(Power Engineers, Inc. 2005c). Four commercial apiaries are located near the proposed mining facilities. Commercial apiaries are used for honey production and/or pollination.

3.18.3.5 Housing

In 2010, the U.S. Census Bureau reported that Lincoln County had 11,413 year-round housing units and that Sanders County had 6,678 year-round housing units. These were increases of 22.5 percent in available housing in Lincoln County and 26.7 percent in Sanders County since 2000. Overall, the percent of owner-occupied housing units in both counties (about 76.2 percent in Lincoln County and 75.1 percent in Sanders County) was higher than the state's 68 percent in 2010.

3.18.3.6 Public Services and Infrastructure

3.18.3.6.1 Schools

Eight elementary schools, eight middle schools, and three high schools are located in Lincoln County. Troy, Libby, and Eureka have an elementary, middle, and high school each. Fortine, McCormick, Sylvanite, Yaak and Trego have an elementary/middle school each. Total school enrollment for public schools in Lincoln County declined by 22.9 percent between 2000 and 2010. In 2011, Libby K-12 Schools consolidated their middle and high schools.

3.18.3.6.2 Law Enforcement

Law enforcement services in the Lincoln County study area are provided by the Lincoln County Sheriff's Office, the Montana Highway Patrol, the Eureka Police Department, the Troy Police Department, and the Libby Police Department. Twenty-one full-time law enforcement officers were employed in Lincoln County in 2003. Two jail facilities occur within the study area: a 24-cell adult jail in Libby; and a 4-bed juvenile holding facility in Troy.

3.18.3.6.3 Fire Protection

Fire protection in Lincoln County is provided by nine fire departments. The rural/city Libby Fire Department has two fire marshals and 29 volunteers, and the Troy rural/city Fire Department has 25 volunteers. The Montana DNRC and the Forest Service are responsible for fire protection in lands under their jurisdictions.

3.18.3.6.4 Health Care Facilities

The healthcare needs of Lincoln County are provided by St. John's Lutheran Hospital, Northwest Community Health Center, Libby Clinic, The Center for Asbestos Related Disease, Libby Care Center, Troy Medical Arts Building, and multiple dental practices. In 2012, St. John's Lutheran Hospital began construction of a new hospital located adjacent to the existing hospital. The hospital will retain its status as a 25-bed Critical Access Hospital with the new construction.

3.18.3.6.5 Water Supply

More than 50 percent of the households in Lincoln County use private wells for their water supply. About 4,750 households in Libby; 1,000 households in Troy; and 1,100 households in Eureka are served by a municipal water system. Libby obtains its water from Flower Creek. Troy receives its municipal water supply from two wells and O'Brien Creek.

3.18.3.6.6 Wastewater Treatment

Libby has operated a public wastewater treatment facility since 1964 and converted from a primary to a secondary treatment facility (*i.e.*, an activated sludge oxidation ditch system) in 1985. In Troy, sewer service is obtained for a fee of $36.27 per month for residential and $40.97 per month for commercial service.

3.18.3.6.7 Utilities

Residential telephone service in the Lincoln County study area is provided by Frontier, a subsidiary of Citizens Communications. The long distance service is provided by AT&T. Electric service for Libby is provided by Flathead Electric Cooperative. Lincoln Electric Cooperative is an electric distribution cooperative headquartered in Eureka, providing electricity service to northeast Lincoln County. Northern Energy provides propane to the local area. Northern Lights, Inc. is the electricity provider in the Troy area. Heating sources in the analysis area include oil, propane, wood, and electricity.

3.18.3.7 Fiscal Conditions

The proposed project would affect the public budgets of Lincoln and Sanders counties; Libby, Troy, Eureka; and those cities' school districts. Basic descriptions of key budget areas for each of these jurisdictions are presented in the following sections.

3.18.3.7.1 Lincoln County

Taxable valuation for Lincoln County increased from $30.78 million in FY 2009 to $31.24 million in FY 2010. This is an increase of $460,000, or 1.5 percent. Countywide levies increased slightly, from 115.85 mills in FY 2009 to 115.95 mills in FY 2010. Total funds appropriated for Lincoln County in 2011 were $6.05 million, representing a 17.8 percent increase over the period from 2007 to 2011 (Montana State University 2011).

3.18.3.7.2 Municipalities

Taxable valuation for Libby was $2.8 million in 2010. From 2006 to 2010, taxable valuation for Libby increased 12.8 percent. Taxable valuation for Libby in 2011 remained at $2.8 million. Total funds appropriated for Libby for 2010 were $1.31 million, representing a 27.2 percent increase from 2006 to 2010. Total funds appropriated in 2011 were $1.33 million.

Taxable valuation for Troy was $772,830 in 2010. From 2006 to 2010, taxable valuation for Troy increased 6.1 percent. Taxable valuation for Troy in 2011 increased to $796,890. Total funds appropriated for Troy for 2010 were $537,880, representing a 43.5 percent increase from 2006 to 2010. Total funds appropriated in 2011 were $529,700. Taxable valuation for Eureka was $987,820 in 2010. From 2006 to 2010, taxable valuation for Eureka increased 5.9 percent. Taxable valuation for Eureka in 2011 increased to $993,830. Total funds appropriated for Eureka for 2010 were $357,350, representing a 67.8 percent decrease from 2006 to 2010. Total funds appropriated in 2011 decreased further to $301,702.

3.18.3.7.3 School Districts

The taxable valuation for all school districts in Lincoln County increased from $30.75 million in FY 2009 to $33.79 million in FY 2011. Countywide mill levies to support schools have remained at about the same level since the early 1990s. Taxable valuation for Troy Public Schools experienced a slight decline from FY 2009 to FY 2010 compared to the other school districts in the County. Taxable valuation for the elementary school declined by 1.1 percent, from $5.49

million in 2009 to $5.43 million in 2010 and then increased to $6.25 million in 2011. Troy High School The taxable valuation for Troy High School declined 3.5 percent, from $6.97 million in 2009 to $6.93 million in 2010. Taxable valuation for Libby K-12 Public Schools experienced an increase of 5.4 percent, from $12.3 million in 2009 to $12.97 million in 2011 (Lincoln County Superintendent of Schools 2009, 2010, 2011).

From 2009 to 2011, Eureka Public Schools experienced an increase of 11.8 percent for the elementary school in taxable valuation, increasing from $8.97 million in FY 2009 to $10.03 million in 2011. Taxable valuation for Fortine Elementary School experienced an increase of 10 percent, from $1.3 million in 2009 to $1.43 million in FY 2011. Taxable valuation for McCormick-Sylvanite Elementary School experienced an increase of 34.8 percent, from $678,646 in FY 2009 to $914,862 in FY 2011. Taxable valuation for Yaak Elementary School experienced an increase of 10.1 percent, from $669,172 in FY 2009 to $736,484 in 2011 (Lincoln County Superintendent of Schools 2009, 2010, 2011).

3.18.3.7.4 Sanders County

Total taxable valuation in Sanders County increased from $31.82 million in FY 2009 to $33.29 million in FY 2010. This is an increase of $1.47 million, or 4.6 percent. Countywide levies decreased, from 97.66 mills in FY 2009 to 96.65 mills in FY 2010. Total funds appropriated for Sanders County increased in 2011 were $10.76 million, representing a 13.1 percent decrease over the period from 2007 to 2011 (Montana State University 2011).

3.18.3.8 Quality of Life and Lifestyle

Social structure and interaction in Lincoln County have been shaped primarily by geographic isolation, migration, and settlement; a resource-extractive economy; global influences on the economy; and a cyclical economy. A cultural overview for the analysis area is provided in section 3.7*, Cultural Resources*.

Libby area residents have adapted to the cyclic nature of the economy by living off the land (*i.e.*, hunting, fishing, gardening, firewood gathering, and berry picking). Local residents tend to acquire vehicles, homes, and other possessions that are functional rather than ostentatious (Western Economic Services, LLC 2006). Residents of Lincoln County, because of their livelihoods, are closely linked to the natural environment and have a conservation ethic. Residents do not favor preservation that would prohibit development of natural resources, but rather favor promoting stability through healthy local economies, lifestyles, and use of natural resources in a sustainable fashion.

A quality of life survey conducted with Lincoln County residents indicates that residents highly valued the natural environment and rural, small town atmosphere of the area (Western Economic Services, LLC 2006). Limited economic opportunities were cited as the largest drawback of the area, although residents felt positive about Lincoln County as a place to live.

Community services were generally viewed as average, with the exception of fire protection and rescue, which were rated above average. Day-to-day shopping varied from Libby, to Kalispell, Missoula, or other avenues such as catalogues and the internet, and respondents cited the limited selection of goods as a drawback to local businesses. Shopping for major purchases was generally done in Libby, Spokane, or Missoula.

Social problems in the area reported by survey respondents include drug and alcohol abuse, family problems or domestic abuse, poverty, and unemployment. Alcoholism and drug abuse were cited most frequently by about half of the respondents. Libby is also now in the midst of addressing hundreds of deaths and illnesses linked to former vermiculite mining operations.

In the 1920s, mining of a large vermiculite deposit north of Libby began. W.R. Grace owned and operated a vermiculite mine and vermiculite processing facilities in Libby from 1963 to 1990. The vermiculite deposits in Libby were contaminated with a form of asbestos similar to tremolite. Asbestos is regulated under the Clean Air Act as a hazardous air pollutant. Studies have shown that exposure to asbestos can cause life-threatening diseases, including asbestosis, lung cancer and mesothelioma. Mining and processing activities resulted in the spread of vermiculite – and the associated asbestos fibers – to numerous homes, businesses, and schools throughout the town. In addition, children played in the discarded batches, and local residents brought home bags of vermiculite to pour into attics for insulation or use in their gardens. Health studies on residents of the Libby area show increased incidence of many types of asbestos-related disease, including a rate of lung cancer that is 30 percent higher than expected when compared with rates in other areas of Montana and the United States. The health problems resulting from the vermiculite mine have resulted in premature deaths, increased health costs, and social division in the Libby area.

The analysis area, like much of the Intermountain West, has seen an increase in rural residences. Many of these rural residences are second homes. The census does not count second-home owners as part of a community's population, thus the impacts of second homes are not readily apparent from changes in population. These second homes can have an impact on local government finances and quality of life issues.

Tourism in the analysis area is a growing industry as it is in all of Montana. Lincoln County is seeking to diversify its economy from mining and timber, and tourism promises to become more important to the area's economic well-being. Multiple efforts are underway to increase the tourism based income in Lincoln County (Lincoln County 2009).

3.18.4 Environmental Consequences

The socioeconomic effects for the No Action Alternatives and the action alternatives were evaluated. The impacts for all of the action alternatives would be the same, so the discussion of Alternatives 2 through 4 and the transmission line alternatives, which include the Sedlak Park Substation and loop line, were combined.

3.18.4.1 Alternative 1 – No Mine and Alternative A – No Transmission Line

In the No Action alternatives for the mine and the transmission line, the proposed mine, transmission line, and Sedlak Park Substation and loop line would not be built, and existing patterns and trends described in section 3.18.3, *Affected Environment* would continue to drive the social structure and economy of the area. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Economic effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

3.18.4.2 All Action Mine and Transmission Line Alternatives

3.18.4.2.1 Employment and Income Effects

The USDA Forest Service produced an analysis of potential employment and labor income effects from the proposed Montanore Project during specific years within the four project phases (termed the "Forest Service Effects Analysis" in this section) for use in this EIS (USDA Forest Service 2007c; updated 2012). The Forest Service Effects Analysis estimates employment and labor income of the proposed project during specific years within the four project phases:

- Construction Phase at Year 3 of the proposed project (peak employment during the Construction Phase)
- Production phase at project Years 4 through 19
- Post-mining Closure Phase at Years 20 through 22
- Reclamation and monitoring phase at Years 23 through 42

Project employment and income and the duration of the mine-life phases could vary from projections, depending upon construction progress and the resources applied by MMC toward full-scale operations. Mineral and input market conditions also could cause operations to be curtailed or shut down on short notice at any point during projected mine life.

Employment and income impacts were estimated in the Forest Service Effects Analysis using input-output analysis. Input-output analysis is a means of examining relationships within an economy between businesses, and between businesses and final consumers. Three types of economic impacts (effects) are identified in the analysis: direct, indirect, and induced. Direct effects are production changes associated with the immediate effects of changes in expenditure tied to mine construction, production, post-mining closure, and reclamation/monitoring. Indirect effects are production changes resulting from spending in all phases of operations in industries that supply products and services to construction, production, mine closure, and reclamation and monitoring. Induced effects are changes in economic activity resulting from households spending income earned directly or indirectly as a result of all phases of the proposed project. The sum of indirect and induced effects are referred to as secondary effects, which is the term used in the remainder of the discussion.

Direct employment and labor income effects were estimated using information provided by MMC and a previous EIS for the Montanore Project (USDA Forest Service *et al*. 1992). Indirect effects were estimated using non-labor expenditure information provided by MMC and IMPLAN (MIG 2004). Induced effects were estimated using IMPLAN. Other specific information on the methodological approach and assumptions used in the analysis presented below can be found within the Forest Service Effects Analysis report. Projected employment and labor income effects identified in the Forest Service Effects Analysis are presented below.

3.18.4.2.2 Construction and Production Employment and Income Effects

The estimated total employment during the Construction Phase of the proposed project would be 623 jobs at Year 3 (Table 158). About 21 percent of the direct employment would be construction related and the remainder attributable to production. The input-output model estimated that there would be about 312 secondary jobs associated with the estimated 311 direct jobs related to construction and operations.

Employment during the production phase would vary with the production rate (Table 158). For production Years 4 through 8, total employment would vary from about 547 jobs in Year 4 to about 447 jobs in Years 5 through 8. After construction is completed but before reaching full production, fewer employees are needed than for the Construction Phase. Secondary employment would account for about 236 jobs in Year 4 and would drop to about 201 jobs during Years 5 through 8. In Year 9, the production rate is expected to increase from 12,500 tons per day to 17,000 tons per day. Direct mine employment would increase from 246 jobs to 450 jobs during this production increase. Secondary employment also would increase from about 201 jobs to 336 jobs. At Year 14, production is expected to increase from 17,000 tons per day to 20,000 tons per day. When production increased, direct employment would remain at 450 jobs and secondary employment would increase slightly.

Table 158. Construction and Production Employment Estimates.

Category	Construction Phase	Production Phase			
Project Year	**3**	**4**	**5-8**	**9-13**	**14-19**
Production rate (tons per day)	0	12,500	12,500	17,000	20,000
Employment					
Construction (direct)	65[†]	65[†]	0	0	0
Operations (direct)	246	246	246	450	450
Secondary employment	312	236	201	336	352
Total construction and operations	623	547	447	786	802

[†]Includes estimated 23-person crew required for construction of the 230-kV transmission line.
Source: MMC 2008.

At Year 3 of the proposed project, direct labor income would be about $42.7 million and total labor income would be $50.3 million (Table 159). About 21 percent of the direct labor income would be construction related and the remainder is attributable to production. The 23-person crew required for construction of the 230-kV transmission line would account for about 35 percent or $3.1 million of the direct labor income for construction in Year 3. Estimated total labor income would range from a low of $39.3 million/per year in project Years 5 through 8 to a peak of $63.5 million per year in Years 14 through 19 during the production phase. The increased labor income would correspond to the expansion in mine production. In general, estimated total labor income would exceed $39 million annually. On a per-job basis, direct annual labor income for construction and operations employment would average about $137,000 and $113,000, respectively. Annual labor income for secondary employment would be about $36,000 per job.

Table 159. Construction and Production Annual Labor Income Estimates.

Category	Peak Construction Phase	Production Phase			
Project Year	**3**	**4**	**5-8**	**9-13**	**14-19**
Production rate (tpd)	0	12,500	12,500	17,000	20,000
Labor Income					
Construction (direct)	$8.9	$6.6	$0.0	$0.0	$0.0
Operations (direct)	$33.8	$25.1	$31.8	$43.2	$50.8
Secondary labor income	$7.6	$8.3	$7.5	$11.7	$12.7
Total construction and operations income	$50.3	$40.0	$39.3	$54.9	$63.5

Income shown in 2010 Million $. Actual totals may differ from values shown due to rounding.
Source: USDA Forest Service 2007c; updated 2012.

3.18.4.2.3 Post-mining Closure, and Reclamation and Monitoring Employment and Income Effects

MMC expects the post-mining Closure Phase of the proposed project to last about 3 years. Total employment would be about 227 jobs for the first 2 years and would decline to about 129 jobs in the third year (Table 160). Secondary employment would account for about 37 percent of the total employment during the post-mining Closure Phase.

The reclamation and monitoring phase of the proposed project would follow the post-mining phase and last about 20 years. This phase also would include consolidation of the tailings and placement of the final cover on the tailings impoundment described in section 2.4.3.1.6, *Tailings Impoundment and Borrow Areas*. Total employment (about 79 jobs) would peak in the first 2 years of this phase and decline to about 32 jobs thereafter. Secondary employment would account for about 37 percent of the total employment during this phase of the proposed project. The second phase would consist of longer-term maintenance of specific facilities, such as the Libby Adit Water Treatment Plant or the seepage collection facilities at the tailings impoundment. MMC would maintain and operate these facilities until BHES Order limits or applicable nondegradation criteria in all receiving waters could be met by any project discharge. MMC also would continue monitoring as long as the MPDES permit is in effect. As long as post-closure water treatment operated, the agencies would require a bond for the operation and maintenance of the water treatment plant. Human activity associated with facility maintenance and monitoring is expected to be limited and indistinguishable from current recreational use. The length of time that the second phase of closure activities would occur is not known but may be decades or more.

Table 160. Post-mining and Reclamation Employment Estimates.

Category	Post-mining Closure Phase			Reclamation and Monitoring Phase		
Project Year	**20**	**21**	**22**	**23**	**24**	**25-42**
Contractors (direct)	0	75	50	25[†]	25[†]	10
Company workforce (direct)	125	50	25	25	25	10
Secondary employment	102	92	54	29	29	12
Total contractors and company	227	217	129	79	79	32

[†] Includes estimated 23-person crew required for removal of the 230-kV transmission line.
Source: MMC 2008 and USDA Forest Service 2007c; updated 2012.

Table 161 provides estimated labor income in 2010 dollars for the post-mining closure, and reclamation and monitoring phase of the proposed project. Direct labor income was based on a workforce consisting of operations, technical, administrative, and environmental services skills. Total labor income during the post-mining phase of the proposed project would be about $16.2 and $14.7 million for the first and second year respectively and would decline to about $8.7 million in the third year. Secondary labor income accounts for about 14 percent of the total labor income during the post-mining Closure Phase.

Total labor income (about $4.7 million) would peak in the first 2 years of the reclamation and monitoring phase, and would decline to about $1.8 million thereafter. The 23-person crew required for removal of the 230-kV transmission line would account for about 92 percent or $2.6 million of the total labor income for direct contractors in each of the first 2 years of the reclamation and monitoring phase. Secondary labor income accounts for about 15 percent of the total labor income during this phase of the proposed project.

Table 161. Post-mining and Reclamation Labor Income Estimates.

Category	Post-mining Closure Phase			Reclamation and Monitoring Phase		
Project Year	**20**	**21**	**22**	**23**	**24**	**25-42**
Contractors (direct)	$0.0	$6.9	$4.6	$1.2	$1.2	$0.5
Company workforce (direct)	$14.1	$5.7	$2.8	$2.8	$2.8	$1.1
Secondary labor income	$2.1	$2.1	$1.3	$0.7	$0.7	$0.2
Total contractors and company income	$16.2	$14.7	$8.7	$4.7	$4.7	$1.8

Income shown in 2010 Million $. Actual totals may differ from values shown due to rounding.
Source: USDA Forest Service 2007c; updated 2012.

The mine would become one of the largest single employers in the area, so any changes in operation or production would impact employment levels. Once the local economy had adjusted to a particular operating level, any reductions-in-force would release individuals whose life style would be attuned to mine wage rates and who would find very few opportunities for comparable employment in the local market. Any shutdown of operations for a few weeks or months would cause a sudden drop in local area income while laid off workers, expecting a resumption of operations, would be unlikely to seek other work. While the affected communities, government jurisdictions, and businesses can plan for mine closure, effects of closure after the planned 20-year production period would decrease employment earnings. Unless other large mining projects are operating in the area at the time, closure of the Montanore mine would eliminate many of the resource commodity sector jobs expected to exist in the local area economy in 2030.

3.18.4.2.4 Population Effects

The employment and income effects analysis summarized above assumed that all direct employment demand would be met from the Lincoln County labor supply. This assumption scenario could occur if a large local population, or a high rate of unemployment in the relevant skill sets, provided a large pool of available labor. Lincoln County does have a higher than average unemployment rate in comparison to neighboring counties and the state as a whole, but given the number of workers needed and the specialized skills required for the construction and production phases of the proposed project, all employment demand may not be met by Lincoln County residents. If that happens, some mine workers may move to the area or commute from locations outside of Lincoln County.

Recent experience for large projects indicates that mining and construction workers will tolerate one-way commuting times of about one hour. Beyond that distance, workers may be more likely to relocate closer to the project site (USDA Forest Service and DEQ 2001). For the Montanore Project, this implies a local employment area that could include all of Lincoln County including the towns of Libby, Troy, and Eureka. If non-local workers (*e.g.*, residents outside of Lincoln County) were to move into Lincoln County for project-related jobs, population within Lincoln County would increase above the baseline projections described in the *Affected Environment* section.

Since the proposed Montanore Project is classified as a "large-scale mineral development," according to the requirements in the Montana Hard-Rock Mining Impact Act, the project proponent is required to evaluate potential impacts on affected local government units as a result of in-migrating workers and their families and prepare a Hard-Rock Mining Impact Plan (Impact Plan). The Impact Plan for the Montanore Project was prepared in 2005 and approved by Lincoln County in 2007. The Impact Plan estimates the number of in-migrating direct and secondary workers and their family members associated with the project. Net in-migration in the first year would be 171 people, and is expected to peak to a net of an additional 429 people in the fourth year of the project at the beginning of the production phase and level off for the rest of the production years (Table 162).

Table 162. Estimated Net Population In-Migration into Lincoln County by Project Year.

Category	Construction Phase			Production Phase		Total
Project Year	**1**	**2**	**3**	**4**	**5**	**1 to 5**
Project Workers	43	81	97	98	92	411
Worker's Family	64	139	191	193	195	782
Secondary Workers and Family	65	118	138	139	126	586
Total	172	338	426	430	413	1,779
Percent Addition to 2010 Lincoln County Population (19,687)	0.9%	1.7%	2.2%	2.2%	2.1%	9.0%

Source: Western Economic Services, LLC 2005.

3.18.4.2.5 Community Effects

The Impact Plan projected the allocations of in-migrating population to various settlement locations in Lincoln County including Libby, Troy, Eureka, and rural areas. In-migration in rural Lincoln County would be a net of 110 people in Year 1, and peak in Year 4 to a net of an additional 275 people. About one-third of the net in-migrating population is expected to settle in Libby (Table 163).

The in-migration projections above incorporate the expectation that housing would be the primary limiting factor for the settlement of in-migrating workers, at least during early project years. Specifically, these projections assume that, with or without assistance from MMC, some temporary housing facilities would be developed on private lands. Such facilities would enable more workers to settle in this area than existing housing allows. Development of new housing on private lands to meet the needs of the entire expected non-local contract construction labor force is unlikely. Because of housing constraints, many would be forced to commute longer distances. Individuals hired for long-term mine jobs may initially have difficulty finding local housing depending on the housing stock available following the preliminary wave of hiring. Some would have to settle initially in communities farther from the mine and then relocate to permanent residences in the Libby/Troy/Eureka area after contract construction workers had left the area (Western Economic Services, LLC 2005).

As noted in the Alternatives 1 and A, discussion of land use trends, population growth in the area is converting areas of private land from timber or agricultural production and open space use into residential subdivisions and ranchettes. The demand on public land resources is also shifting away from traditional resource commodity production toward a greater emphasis on recreation, and aesthetic values. Mine development would add to population and housing demand pressures. Land use demand driven by mine development would differ somewhat from the existing pattern driven by retiree and recreation/tourism/amenity in-migrant population growth. Barring mine shutdowns, mine operations workers would have the kind of jobs with above-average wages that would allow them to purchase or build homes. Some in-migrants hired into secondary and replacement jobs would be in the same situation. Others would be more likely to prefer rental housing or mobile home spaces. In-migration during mine operations would place less strain on local housing supplies than would the earlier influx of construction workers. The development of local businesses catering to new residential areas and commuting mine workers also is expected.

Table 163. Expected Net In-Migrating Population Settlement Locations by Project Year.

Category	Construction Phase			Production Phase		Total§
Project Year	1	2	3	4	5	1 to 5
Direct Construction and Production Employees and Families						
Libby	35	72	94	95	94	390
Troy	2	5	6	6	6	25
Eureka	1	2	3	3	3	12
Rural Lincoln County†	69	141	184	186	183	763

Rural Lincoln County	41	76	89	89	81	376
Total	64	119	138	139	126	586
Combined Total Net In-Migration by Area						
Libby	56	111	139	141	135	582
Troy	3	8	9	9	9	38
Eureka	2	3	4	4	4	17
Rural Lincoln County	110	217	273	275	264	1,139
Total	171	339	425	429	412	1,776

§Total in Table 162 varies from the total in Table 163 due to rounding.
†Lincoln County is predominantly a rural county. Urban development is concentrated in the incorporated areas of Eureka, Libby, Rexford and Troy.
Source: Western Economic Services, LLC 2005.

While some construction in-migrants is expected to become long-term residents and would seek to become integrated into the community, others would be well aware of their temporary status and unlikely to participate. An influx of temporary residents with large cash incomes, few ties to the community, and limited social activities in which to engage may pose problems for limited law enforcement resources. The extent these phenomena would surface in the western Lincoln County communities is difficult to predict. The agencies expect some detrimental effects from the influx and departure of the large contract construction workforce. Large influxes of workers and their families would likely impact the social structure of Libby, Troy and surrounding rural areas in terms of local values, school attendance, and community character. Such incoming workers may or may not share the local values of the area and may not have as strong of ties on average to the community as long-time residents. Also, large influxes and/or out-migrations of workers could disrupt both the local social fabric of communities like Libby and their economic viability (both positively and negatively). The Bakken shale development in eastern Montana and North Dakota is an extreme example of some of these impacts, with such impacts from Montanore expected to be much smaller. It is possible that a few longtime residents could leave the area as a result of the influx of workers, but that number would likely be low.

3.18.4.2.6 Public Services

Local governments would need to serve fluctuating populations. Impacts on specific local governmental units within the study area due to in-migrating workers and their families depend entirely upon where the in-migrants choose to reside. In addition to housing-related factors affecting settlement patterns, in-migrants also would consider the availability of public services in making their residency choices.

Local government service-providers would have to respond to an estimated 171 net in-migrants in the first year of mine construction and an expected peak in the fourth project year of an additional 429 total net in-migrants. The population increases during mine startup could cause difficulty for some service providers in responding to demands, requiring change in staffing and resource allocation. Because Lincoln County school enrollments were projected to decline over the next 10 to 15 years (if the mine were not developed), the arrival of students associated with mine operations would not be expected to pose an enrollment problem for the school system. There may be some challenges with staffing and maintaining appropriate classroom size with the addition of new students.

Small communities that lack temporary housing facilities as well as a wide range of public and private services may experience law enforcement problems when a large temporary work force with no community ties, above-average income, marginal housing, and a high percentage of individuals who are not accompanied by families suddenly arrives. If such problems were to develop in association with the startup Construction Phase of the Montanore Project, the problems would be more likely to occur in the communities located nearest to the mine site based on the probable settlement patterns of the work force.

Community fire, emergency, medical, and social service providers may have a hard time adjusting their staffing to the increases in service demands associated with mine construction and startup. Obtaining and training new staff takes time, and the fire and ambulance services, in particular, could experience difficulty finding and training additional volunteers. Any fiscal impacts on local government service providers would be mitigated through payments as established in the Hard Rock Mining Impact Plan (Western Economic Services 2005). These service providers would benefit from the additional tax revenues generated by the mine and should be able to adapt to the long-term changes in demand associated with mine operations. It is anticipated that the mine would maintain its own ambulance and would support and cooperate with local emergency service providers.

3.18.4.2.7 Fiscal Effects

The proposed project would increase local and state government revenues and expenses. The Impact Plan included an analysis of project-related revenues and costs to affected local governments from the mine operations and population increases. Affected local government units within the defined Impact Plan study area include:

- Lincoln County Government (including special districts)
- City of Libby
- City of Troy
- City of Eureka
- Libby School District
- Troy Elementary School District

- Troy High School District
- Eureka Elementary School District
- Lincoln County High School District

New project-related revenues to local governments would come from three primary sources: property taxes on the mine land, plant, and equipment; the gross proceeds tax on the value of ore produced; and property taxes on new homes and commercial facilities built as a result of mine development. The project would increase costs for cities, schools, and counties through mine-related in-migration and resulting increases in local government service costs. The additional tax revenue would largely be used by local governments to pay for capital outlays, personnel, and support costs.

Lincoln County and the Libby, Troy, and Eureka school districts would be the primary recipients of tax revenues from the mine and mill facilities, but Montana law provides for tax-base sharing among affected Montana local government units when a mine is designated as a large-scale mineral development.

When construction of mine facilities was completed, the property tax revenue would be about $2.35 million represented by the land and improvements (*i.e.*, Class 4 property) and all the business equipment (*i.e.*, Class 8 property) (Western Economic Services, LLC 2005). The overall tax revenue would decline as the mine facilities and equipment portion depreciated, reaching fully depreciated values in 10 to 15 years. Annual local tax revenues would depend on local mill levy rates, state property tax equalization, and property tax prepayments and credits.

Montana levies a metal mines license tax on a mine's annual gross revenues in excess of $250,000. This is a percentage tax on the value of ore concentrate shipped to the refinery. Tax revenues would fluctuate depending on silver and copper prices and the project's annual production levels. By law, 75 percent of these revenues would be allocated to Montana's general fund. The remaining 25 percent would be allocated to Lincoln County, and distributed through the county to appropriate departments and districts. The county would be required to reserve at least 37.5 percent of this revenue in a trust fund account. All money not allocated to the trust fund account is distributed as follows; 33.3 percent to elementary school districts, 33.3 percent to high school districts, and 33.3 percent for general planning functions (*e.g.*, economic development activities).

Table 164 summarizes projected fiscal effects from the project. Net impact on local governments would start with a $180,242 deficit in Year 1, followed by net surpluses starting in Year 2 with a net surplus of about $4.8 million in Year 5. MMC's proposed mitigation of $180,000 would mitigate for the Year 1 fiscal deficit. While Sanders County would not have workers migrating into the county due directly or indirectly to the Montanore Project, Sanders County would receive $208,000 in gross proceeds tax in Year 4 and $546,000 in Year 5 (Western Economic Services, LLC 2005). The projected fiscal effects shown in Table 164 should be considered a representative estimate of actual fiscal effects, which would depend on a number of currently unknown factors and future local government conditions.

3.18.4.2.8 Quality of Life and Lifestyle

In addition to the effects disclosed in the *Community Effects* section, the Montanore Project would have minor effects on social well-being and quality of life in the analysis area. Mining and other natural resource development has been an important part of the local economy for many years. The ongoing national and regional growth of recreation and tourism would also be a factor, as recreation/tourism would continue to help shape the economy in the analysis area. The analysis area, which is accustomed to yearly recreation and tourism booms, should be able to accommodate the projected short-term mine construction population influx with little difficulty even if the mine construction peak coincides with the peak tourism season. Individuals and social groups within the community would perceive project-related benefits, such as increased economic opportunity, and costs such as social problems associated with population growth, from the variable perspective of their own values, beliefs, and goals. Such perceptions would of course vary. Increased income within the analysis area would create new opportunities in the retail sales and service sector. Some residents believe the proposed project would revitalize and stabilize the depressed local economy.

Table 164. Net Local Government Fiscal Impact due to Montanore.

Category	Construction Phase			Production Phase	
Project Year	**1**	**2**	**3**	**4**	**5**
Costs					
Direct Worker Local Government Costs	$253,797	$563,239	$786,312	$798,962	$813,366
Indirect Worker Local Government Costs	$128,987	$236,679	$277,825	$281,063	$255,531
Total Costs to Units of Local Government	**$382,784**	**$799,918**	**$1,064,137**	**$1,080,025**	**$1,068,897**
Revenues					
Montanore Taxes:					
Metal Mines License Tax (to Lincoln County[†])	0	0	0	$215,000	$565,000
Gross Proceeds Metal Mines Tax (to Lincoln County[‡])	0	0	0	$832,000	$2,184,000
Gross Proceeds Metal Mines Tax (to Sanders County)	0	0	0	$208,000	$546,000
Montana Property Tax (land & improvements)	$10,000	$740,000	$1,290,000	$2,060,000	$2,060,000
Montana Property Tax (business equipment)	$80,000	$150,000	$210,000	$290,000	$290,000
Indirect Worker - Commercial Property Tax	$12,998	$23,774	$27,787	$28,017	$25,355
Direct Worker - Commercial Property Tax	$21,549	$44,204	$57,778	$58,445	$57,568
Indirect Workers - Residential Property Tax	$32,419	$59,296	$69,307	$69,880	$63,241
Direct Workers - Residential Property Tax	$45,576	$85,212	$102,036	$103,163	$97,269
Total	**$202,541**	**$1,102,485**	**$1,756,908**	**$3,864,505**	**$5,888,432**
Impact	**$-180,242**	**$302,567**	**$692,771**	**$2,784,479**	**$4,819,535**

[†]According to MCA 15-1-501 the Montana Metal Mines License Tax is allocated as follows: 57 percent to the state general fund, 2.5 percent to the hard rock mining impact trust account, 8.5 percent to the hard rock mining reclamation debt service fund, 7.0 percent to the reclamation and development grants program state special revenue account, and 25.0 percent to the county or counties identified as experiencing fiscal and economic impacts.
[‡]The allocation of the Montana Gross Proceeds Tax, a Class 2 Property Tax, was settled in the early 1990s.
Source: Western Economic Services, LLC 2005.

Negative perceptions of project development may be attributed to people with various other points of view. Many residents express anxiety at the prospect of a major mineral development project, based on their experience with and perceptions of other mining projects. These concerns primarily are that the Montanore Project might generate similar problems, and that state and federal agencies might not adequately monitor and enforce applicable laws and regulations. Persons having these views want their feelings known, but are not necessarily opposed to development of the Montanore Project. Projections for increased housing demand during mine development and operation suggest that most property values (including second homes) in the area would increase, but the value of some specific parcels or types of properties could be affected negatively for some periods during mine construction, operation, and reclamation. It is also possible that the use of a parcel to its current owner, that is its ability to serve the specific purposes for which the property was purchased, may be impacted negatively even though its potential market value may not decrease.

3.18.4.3 Effectiveness of Agencies' Proposed Mitigation

Implementation of the 2005 Hard Rock Mining Impact Plan (Western Economic Services 2005) would effectively mitigate for financial impacts on local governments from the proposed project.

3.18.4.4 Cumulative Effects

In addition to the proposed Montanore Project, the proposed Rock Creek Project would affect Lincoln County. Other mineral activities in the area (*i.e.*, primarily small exploration projects) and the regional timber industry are not expected to lead to major developments in the reasonably foreseeable future.

The Rock Creek Project is a proposed underground copper and silver mine and mill/concentrator complex near Noxon, in Sanders County, Montana. The project is owned by Revett. The nearest town to the proposed Rock Creek development is Noxon, an unincorporated town on MT 200 in Sanders County. Access to the Rock Creek mine would be from the Noxon area, and mine facilities also would be located in Sanders County.

The KNF is preparing a Supplemental Environmental Impact Statement (EIS) for the Rock Creek Project to address deficiencies identified by a Federal District Court in a 2001 Final EIS. The Supplemental EIS also will disclose effects on resources that may be substantially affected by changes in circumstances or new information. Based on the Supplemental EIS and Record of Decision (ROD) schedule and a projected 5-year evaluation and construction period, the earliest the Rock Creek Project could go into production is late 2019. Mine life of the Rock Creek operation is estimated to be 28 years. Annual earnings from direct and secondary mine-related employment would be about $30.3 million during the Construction Phase and $38.8 million during the production phase.

The estimated total annual direct employment during the Construction Phase for the Rock Creek Project would be 232 workers, with an estimated total annual direct employment of 344 employees during operations (USDA Forest Service 2013f). The peak population increase associated with Rock Creek development in the Noxon/Heron/Trout Creek area (*i.e.*, western Sanders County) is projected to be about 328 people during project construction. The projected long-term population increase in the Noxon/Heron/Trout Creek area attributable to the Rock Creek Project is estimated to be about 378 people. The total peak population increase in Lincoln County from the Rock Creek Project during operations is estimated to be about 280 people. Most effects of the Rock Creek Project would occur in the Noxon/Heron/Trout Creek area (USDA Forest Service and DEQ 2001).

A key factor determining the number of in-migrating workers for both the Rock Creek Project and the Montanore Project is the fate of the Troy Mine. The Troy Mine resumed operations in 2004 and, in 2012, has an estimated mine life of 7 years. Exploration at Troy Mine is continuing. Upon closure of the Troy Mine, a skilled workforce of 150 may be available either to the Rock Creek or Montanore projects. Depending on the timing of each project's start-up, there would be some direct competition for former Troy workers. Because much of the Troy Mine workforce already lives in the Libby area, some of these workers is expected to seek employment with MMC at Montanore to avoid the longer commuting distance to the Rock Creek Project. Assuming Troy Mine closure and Rock Creek Project startup are relatively concurrent, many current Troy Mine workers would continue employment with Revett for the Rock Creek operation because of employee seniority and benefit vesting in Revett.

With the availability of the Troy Mine workforce for one or both of the new projects and current unemployment rates in Lincoln and Sanders counties, 80 percent local hiring for both projects would be still possible. The percentage of local hiring would also depend on workers with the correct skills within the unemployed labor force. If only one of the two projects is developed (either Rock Creek or Montanore, but not both), the displaced Troy Mine workforce may provide a substantial amount of the needed production workforce. If Rock Creek is developed, but the Montanore Project is not, some Lincoln County residents currently working at the Troy Mine may migrate to Sanders County to shorten their commute.

If the Troy Mine (with additional reserves extending the mine life), Rock Creek, and Montanore were all to operate concurrently, which is considered a possibility, the Troy Mine workforce would not be available to the two new projects, and the 80 percent local hiring assumption might not be met. This scenario would result in a larger population migration into Sanders and Lincoln counties than would result from the development of only one project. It also would result in the greatest level of community growth and disruption.

Under the most likely situation, no in-migrating workers directly associated with the proposed Montanore Project are expected to reside in Sanders County. The Montanore Project is not expected to have any cumulative effect on population or demand for public services in Sanders County. The gross proceeds tax received by Sanders County could result in some additional employment in the government sector.

3.18.4.5 Regulatory/Forest Plan Consistency

The goal for mineral development in the KFP is to "encourage responsible development of mineral resources in a manner that recognizes national and local needs and provides for economically and environmentally sound exploration, extraction, and reclamation." The proposed Montanore Project would be consistent with this goal outlined in the KFP (USDA Forest Service 1987a). The project would be consistent with the Hard Rock Mining Impact Act following implementation of the approved Hard Rock Mining Impact Plan.

3.18.4.6 Irreversible and Irretrievable Commitments

There would an irreversible commitment of mineral resources under all of the action alternatives. Economic productivity for timber or other resources from mined lands would be irretrievable lost during mine operations.

3.18.4.7 Short-term Uses and Long-term Productivity

In the short term, the project would increase costs for cities, schools, and counties through mine-related in-migration and resulting increases in local government service costs. A short-term increase in population, as well as increases wages, spending, and tax revenue would occur over the life of the mine. The increase in tax revenue along with the commitment in the Hard Rock Mining Impact Plan (Western Economic Services 2005) to pay all increased capital and net operating costs to local government units that would result from the mineral development should offset any increases in local government service costs. Over the long term following mining, population and income levels may decline, as would the cost for local governments to provide services.

3.18.4.8 Unavoidable Adverse Environmental Effects

Under all mine and transmission line alternatives, increased employment and population would place increased demands on housing and some public services, including schools. With mitigation, as outlined in the Hard Rock Mining Impact Plan (Western Economic Services 2005), the increased demands would not result in unavoidable adverse environmental effects.

3.19 Soils and Reclamation

3.19.1 Regulatory Framework

3.19.1.1 Federal Requirements

The KFP requires BMPs on National Forest System lands to limit soil erosion and to maintain soil productivity (USDA Forest Service 1987a). In addition, the regional soil quality standards (FSM 2500 – Watershed and Air Management, R1 Supplement No. 2500-99-1) and Chapter 2550 – Soil Management contains soil management objectives and policies applicable to activities on the KNF. Soil quality standards apply to lands where vegetation and water resource management (*i.e.*, timber sales, grazing pastures or allotments, wildlife habitat, and riparian areas) are the principal objectives. The standards do not apply to intensively developed sites such as mines, developed recreation sites, administrative sites, or rock quarries, as such sites are reallocated to non-timber production management. Reallocation proposed for the Montanore Project area described in section 2.12, *Forest Plan Amendment.* The standards are not intended to prohibit other resource management practices such as installing waterbars or preparing sites for planting, as long as such practices are consistent with long-term sustainability of the soil resource. Permanent roads can affect soil-hydrologic function; their evaluation is more appropriately done on a watershed basis using models and other watershed analysis techniques (FSM 2554.1 R1 Supplement; USDA-ARS National Soil Erosion Research Laboratory 1995). The standards would apply once the mining was complete and the principal objective again became vegetation management. The reclamation plan for the project would include meeting the soil quality standards as one of the long-term reclamation goals. Additional guidance is included in USDA Forest Service's Region 1 NEPA guidance for soils (USDA Forest Service 2011e).

As stated above, areas on National Forest System lands with intense long-term development (*i.e.,* where the vegetation has been removed) are reallocated to non-timber production management, and lands that are changed in management type do not have to meet the 15 percent disturbance standard. As discussed in sections 2.12, *Forest Plan Amendment* and 3.15, *Land Use*, areas to be reallocated to non-timber production management would include the tailings impoundment, plant site, limited disturbances in LAD Areas, and portions of the transmission line corridor where the vegetation would be removed.

The Organic Administration Act authorizes the Forest Service to regulate the occupancy and use of National Forest System lands. The Forest Service's locatable minerals regulations are promulgated at 36 CFR 228, Subpart A. The regulations apply to operations conducted under the U.S. mining laws as they affect surface resources on National Forest System lands under the jurisdiction of the Secretary of Agriculture. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources. 36 CFR 228.8 also requires that mining operators construct and maintain all roads so as to assure adequate drainage and minimize or, where practicable, eliminate damage to soil, water, and other resource values; and reclaim the surface disturbed in operations by taking such measures as preventing or controlling onsite and off-site damage to the environment and forest surface resources. For the Montanore Project, the KNF emphasizes protection of the soil resource and implementation of restoration practices where necessary on National Forest System lands. Standards and BMPs identified in the KFP would be included as mitigation measures where appropriate and would be used to guide MMC's implementation of the project.

3.19.1.2 State Requirements

MMRA requires that all lands disturbed by mining be reclaimed to a post-mine land use that has stability and utility comparable to that of the pre-mining landscape. The DEQ must evaluate MMC's proposed reclamation plan for areas to be revegetated to ensure that the soil needed to reclaim mine site disturbances would be salvaged and replaced, and areas revegetated to comparable stability and utility. The MFSA directs the DEQ to approve a facility if, in conjunction with other findings, the DEQ finds and determines that the facility would minimize adverse environmental impact, considering the state of available technology and the nature and economics of the various alternatives.

3.19.2 Analysis Area and Methods

The analysis area for soils consists of the areas that would be disturbed by facility construction under each alternative and are shown on Figure 83. The Libby Loadout would be in the previously disturbed Kootenai Business Park; therefore, the loadout is not discussed further.

Soil investigations for the mine area facilities and the transmission line corridors were conducted in 1988 and 1989 by NMC to provide soil information for land use management and reclamation (Western Resource Development Corp. 1989b, 1989c). A detailed soil survey using standard USDA soil survey methods was performed in an "intensive study area," which included most of the Little Cherry Creek Tailings Impoundment Site and the Poorman Tailings Impoundment Site, the Ramsey Plant and Libby Adit sites, and most of the two LAD Areas. The "extensive study area" consisted of the proposed access roads, transmission line corridors and Sedlak Park Substation and loop line. Soils information from the KNF soil survey was used for the extensive study area (USDA Forest Service and Natural Resources Conservation Service 1995).

The soil baseline studies contain descriptions of field, laboratory, and interpretation methods (Western Resource Development Corp. 1989b, 1989c). Laboratory analyses were performed for selected physical and chemical parameters of the soils to assist with making interpretations important to mining operations and reclamation. Particle size analysis, percent rock fragments (>2 mm), organic matter percent, soil pH, and percent water at saturation were determined.

Soil interpretations were made for construction, management, and reclamation purposes. For the intensive survey area, soil erodibility, potential slope stability, and soil suitability were determined for each soil map unit. For the extensive study area, soil erodibility, slope failure potential, and revegetation potential were obtained from the KNF soil survey. Because the soils data for the extensive study area are more generalized, soil suitability was extrapolated from the intensive study area to provide more probable site-specific salvageable soil volumes.

Soil baseline studies and interpretations were used to analyze the likely effects for each alternative. Soil suitability was used to determine volumes of salvageable soil to be used for reclamation at each proposed disturbance area. Soil erodibility was used to assess the susceptibility of the soils to erode when disturbed and the likelihood of eroded soil reaching stream channels. Slope failure was used to evaluate soil suitability for road construction and maintenance. Revegetation potential was used to determine if any soils were unsuitable without amendments, and if soils were found to be limited, what amendments would be needed to enhance revegetation potential.

3.19.3 Affected Environment

Soils in the analysis area have been influenced by four geomorphic processes: colluvial (movement downhill as a result of gravity); fluvial (movement by flowing water from streams and rivers); glaciolacustrine (movement or deposition in lakes); and glacial (movement by glaciers). In addition to these four processes, a thin mantle of volcanic ash-influenced loess (fine textured soil deposited by wind) blankets much of the analysis area soils. The loess commonly differs sharply from the soil beneath it and varies in depth based on aspect and elevation. Soil layers formed in loess that have been influenced by volcanic ash or in glacial till have a moderate hazard of erosion. A rating of severe is assigned to soil layers having a sandy texture or a loamy or clayey texture and a content of rock fragments of less than 15 percent, such as soil layers formed in lacustrine deposits or in sandy glacial outwash (USDA Forest Service and Natural Resources Conservation Service 1995). Within the analysis area, the soils vary in age, degree of development, and fertility. Relatively young soils forming in colluvial material generally have little development, are typically high in rock fragment and, generally have low fertility (Western Resource Development Corp. 1989b, 1989c). Soils associated with alluvial processes are also relatively young, have little or no development, have abundant rock fragments, and generally have low fertility. Soils forming in glaciolacustrine sediments are of late-Wisconsin glacial age (10,000-25,000 years before present), show weak to strong development, are typically high in silts and clays with few rock fragments, and have low fertility. Other intermediate aged soils have some development, have low fertility, and have some rock fragments. The oldest soils, associated with continental glaciation, are strongly developed, have clay to silty clay textures, and are some of the more fertile soils in the permit area.

3.19.3.1 Soil Types

Soils within the analysis area can be divided into six general groups based on the parent material and the type of geomorphic process in which they formed (Figure 83). The soil group “colluvial/glacial soils” was mapped only in the intensive study areas; because of the scale of mapping, it is not shown in Figure 83. The six groups are:

- Alluvial soils that formed in rocky alluvium
- Glaciolacustrine soils that formed in fine-textured glaciolacustrine deposits
- Alpine glacial soils that formed in rocky alpine glacial drift
- Continental glacial soils that formed in rocky continental glacial drift
- Residuum/glacial soils that formed in rocky residuum and glacial drift
- Colluvial/glacial soils that formed in rocky colluvium and glacial drift

3.19.3.1.1 Alluvial Soils

The alluvial soils are deep, well drained to very poorly drained, and contain a high amount of rock fragments. They formed in gravelly and cobbly coarse-textured alluvium and have a volcanic ash surface layer. They occur on nearly level to strongly sloping alluvial and glaciofluvial terraces, terrace escarpments, drainage bottoms, old lake beds, and floodplains. These soils are moderately extensive along Poorman, Libby and Bear creeks at the Little Cherry Creek and Poorman Tailings Impoundment sites, the Ramsey Plant Site, the Libby Adit Site, and along the Fisher River valley bottom near the transmission line alignments. Narrow areas of alluvial deposits occur along all streams in the analysis area. Depth to the water table is variable, with some soils saturated most of the year. Included in this soil group within the proposed Little Cherry Creek Tailings Impoundment Site are very poorly drained areas, such as bogs and wet depressions that contain organic-rich soils.

The surface textures are generally loam, gravelly silt loam, and very gravelly sandy loam with 5 to 55 percent rock fragments. Subsoil textures are generally gravelly silt loam, extremely gravelly silt loam, and loamy sand with 15 to 75 percent rock fragments. Rocky colluvial soils occur on many toeslopes within this soil group. Organic matter content is medium to very high (3 percent to greater than 50 percent in some poorly drained areas) in the surface layers and is typically much lower in subsoil layers. The soils are very strongly acid to moderately acid (pH 4.5 to 5.7). Available water holding capacity is low to high, and soil permeability is slow to rapid. Generally, the surface layers of these soils have low to moderate susceptibility to erosion by water and low to high susceptibility below the surface layer. The soils have low to high sediment delivery efficiency, which is the relative probability of eroded soil reaching a stream channel, and they have high slope stability.

3.19.3.1.2 Glaciolacustrine Soils

Glaciolacustrine soils are deep, well drained, and relatively free of rock fragments. They formed in fine-textured glacial lake sediments and have a volcanic ash surface layer. They are found on nearly level to strongly sloping glaciolacustrine terraces and steep to very steep terrace risers. These soils are of moderate extent in the Little Cherry Creek and Poorman Tailings Impoundment sites, and they occur along the transmission line alignments and at the Sedlak Park Substation Site. Included in this soil group within the proposed Little Cherry Creek Tailings Impoundment Site are very poorly drained areas, such as bogs and wet depressions that contain organic-rich soils

The surface textures are generally silt loam with few rock fragments. Subsoil textures are generally silt loam, silty clay loam, and silty clay with few rock fragments. Clay contents in subsoil layers can exceed 45 percent. Organic matter content is medium (2 to 3 percent) in the surface layers and is typically less than 1 percent below the surface layer. The soils are strongly acid to slightly acid (pH 5.4 to 6.2). Available water holding capacity is high, and soil permeability is very slow. Generally, the surface layers of these soils have moderate to high susceptibility to erosion by water and high susceptibility below the surface layer. The soils have low to moderate sediment delivery efficiency. They generally have high slope stability, but exhibit cutbank sloughing on slopes greater than 15 percent.

3.19.3.1.3 Alpine Glacial Soils

Alpine glacial soils are deep, well drained, and contain a large percentage of rock fragments. They formed in gravelly, medium-textured glacial drift and have a surface layer of volcanic ash. They occur at higher elevations on gently to steep glacial moraines and glacial valleys. In places, rock outcrops are extensive within this soil group. These soils are moderately extensive in the valleys at the Ramsey Plant Site, Libby Adit Site, Rock Lake Ventilation Adit, and along the transmission line alignments.

The surface textures are generally gravelly silt loam with about 20 percent rock fragments. Subsoil textures are generally very gravelly silt loam with 40 to 60 percent rock fragments. Organic matter content can be very high in the surface layer due to ash influence, but drops off rapidly to less than 1 percent a few feet below the surface. The soils are generally very strongly acid to strongly acid (pH 5.0 to 5.5). Available water holding capacity is moderate, and soil permeability is moderate to high. Generally, both the surface and subsurface layers have moderate to high susceptibility to erosion by water. The soils have low to high sediment delivery efficiency. They are commonly susceptible to cutbank sloughing and raveling.

3.19.3.1.4 Continental Glacial Soils

Continental glacial soils are deep, well drained, and rocky. They formed in gravelly, fine-textured old glacial drift and have volcanic ash surface horizons. Some soils in this group formed in rocky colluvium. This soil group, which is at lower elevations than the alpine glacial soils, occurs on nearly level to very steep, continentally glaciated plains, mountain side slopes, and ridges. In places, rock outcrops are extensive within this soil group. These soils are very extensive along the transmission line alignments, at the Sedlak Park Substation Site, at the Little Cherry Creek and Poorman Tailings Impoundment sites, making up over half of the impoundment sites, and most of the Libby Plant Site and LAD Areas. Included in this soil group within the proposed tailings impoundment sites are very poorly drained areas, such as bogs and wet depressions that contain organic-rich soils.

The surface textures are generally silt loam, gravelly silt loam, and clay loam with few to 30 percent rock fragments. Subsoil textures are generally very gravelly, moderately fine and fine textures with 10 to 60 percent rock fragments. Clay contents can exceed 60 percent in the subsoil. Organic matter content is medium to high (2 to 5 percent) in the surface layer, but decreases to less than 1 percent below the surface. The soils are generally very strongly acid to moderately acid (pH 4.7 to 5.9) but can be mildly alkaline in the substratum. Available water holding capacity is moderate to high, and soil permeability is very slow to slow. Generally, both the surface and subsurface layers of these soils have moderate to high susceptibility to erosion by water. The soils have low to high sediment delivery efficiency. They are commonly susceptible to cutbank sloughing and landslides can occur in steep drainageways.

3.19.3.1.5 Residuum/Glacial Soils

Residuum/glacial soils are shallow to deep, well drained, and contain a high amount of rock fragments. They formed in gravelly medium textured glacial drift and meta-sedimentary residuum and have a volcanic ash surface layer. They occur on gently sloping to very steep glacial scoured ridge tops, glacial trough walls, and valley side slopes. They are moderately extensive in the Little Cherry Creek and Poorman Tailings Impoundment sites, and they occur along the transmission line alignments.

The surface textures are generally silt loam and gravelly silt loam with few to 30 percent rock fragments. Subsoil textures are generally very gravelly loam with up to 60 percent rock fragments. Rock outcrops occur throughout these soils. Organic matter content is moderately low in the surface layer and low below the surface. The soils are generally very strongly acid to moderately acid (pH 5.2 to 6.0). Available water holding capacity is low, and soil permeability is moderate to rapid. Generally, the surface layers of these soils have moderate susceptibility to erosion by water, and have low susceptibility to erosion by water below the surface layer. These soils have low to high sediment delivery efficiency. They commonly exhibit high slope stability but landslides can occur in steep drainageways, and sloughing and raveling can occur if cutbanks are steep. Avalanche paths occur on some very steep slopes.

3.19.3.1.6 Colluvial/Glacial Soils

The colluvial/glacial soils are moderately deep to deep, well drained, and contain high amounts of rock fragments. They formed in gravelly and cobbly medium textured colluvium and glacial drift and have volcanic ash surface layers. They occur on gently sloping to very steep colluvial and glacial side slopes, ridge tops, in cirque basins (semicircular basins near valley heads in mountains caused by glacial erosion), and in avalanche chutes and debris deposits. These soils are extensive at the Ramsey Plant Site. Several avalanche debris fans are located at the Libby Adit Site.

The surface textures are generally silt loam to extremely gravelly silt loam with 10 to 80 percent rock fragments. Subsoil textures are generally very gravelly silt loam and extremely gravelly loam, silt loam, and sandy loam with 35 to 87 percent rock fragments. Many of these soils have a large amount of stones and boulders covering the surface, and rock outcrops occur as inclusions. Organic matter content is medium to high (3 to 6 percent) in the surface layers and is typically less than 1 to 3 percent in subsoil layers. The soils are strongly acid to slightly acid (pH 5.3 to 6.1) but are extremely acid with a pH of 4.4 in areas at the Libby Adit Site. Available water holding capacity is low to moderate and soil permeability is moderate to rapid. Generally, the surface layers of these soils have low to moderate susceptibility to erosion by water and low susceptibility to erosion by water below the surface layer. The soils have moderate to high sediment delivery efficiency. Generally on shallower slopes (less than 25 to 35 percent), these soils have high slope stability and have moderate to low slope stability on steeper slopes.

3.19.3.2 Suitability for Reclamation

The soils in the analysis area are generally suitable for salvage and replacement. Relatively organic-rich surface layers range from 5 to 29 inches thick and average about 10 inches thick. Subsoils are also suitable for salvage and use in reclamation. Salvageable soil, including both surface soil and subsoil layers, ranges from 9 to 33 inches. Organic matter levels in surface soils are generally moderate to high, and pH values range from 4.4 to 6.6, but are typically between 5 and 6. Because of volcanic ash, the surface layers are typically medium textured and have a high water holding capacity. Some surface layers of colluvial/glacial soils have a moderate water holding capacity. A high water table would preclude salvage of some alluvial soils. Soils on slopes greater than 50 percent are generally unsuitable for salvage mainly because of safety considerations for equipment operators (Plantenberg, pers. comm. 2012).

The primary limitation to soil suitability for reclamation is rock fragment content. Soils with more than 50 percent rock fragments are generally considered unsuitable (Plantenberg, pers. comm. 2012), unless they are needed to control erosion on steep slopes. Surface soils commonly have 10 to 50 percent rock fragments, but glaciolacustrine surface layers are relatively free of rock fragments. Many of the colluvial/glacial soils contain high amounts of stones and boulders on the surface. Salvageable soils with stones and boulders would require special handling. Subsoil layers are more variable in texture and pH, but generally have high amounts of rock fragments, except for glaciolacustrine subsoil layers, which generally lack rock fragments. The soils are rated good to poor for road suitability. Poor ratings are typically due to steep slopes and susceptibility of slope failure. Glaciolacustrine soils are rated poor for road suitability due to slumping, and some alluvial soils are rated poor due to excess water. None of the soils in the analysis area have severe reclamation or revegetation potential constraints, *i.e.* with mitigation, there would be minor losses of soil until re-establishment of vegetation.

3.19.4 Environmental Consequences

This section addresses soil impacts resulting from the action Alternatives 2, 3, and 4. The impacts are typical of any operation where soil would be removed, stored, and replaced. The effects on soils that are common to all action alternatives are presented first, followed by the effects on soils that would be unique to each alternative. Soil impacts resulting from all action alternatives would include:

1) Soil loss from erosion of disturbed areas and losses of salvageable materials through erosion and handling
2) Changes in soil physical, chemical, and biological characteristics
3) Reduction in plant growth due to potentially harmful metals in some subsoils because of the potentially acid pH levels, and in mine wastes that would be part of the revegetated plant community rooting zone

Identification of these impacts, followed by the incorporation of the appropriate mitigation measures included in the project's operating plan and the project's reclamation plan, determine the potential success of reclaiming the land to forest cover and wildlife habitat after operations cease. With respect to soils, limited reclamation success, may result in secondary or long-term negative impacts including soil erosion, and reduced soil/site productivity.

3.19.4.1 Effects Common to All Action Alternatives

3.19.4.1.1 Soil Loss

Areas cleared of vegetation would be susceptible to erosive forces and soil loss. Loss of soil also would occur from the removal and storage of soils during mine operations and from erosion of exposed soils during reclamation and stabilization. The potential for soil erosion caused by wind or water exists during all phases of the project. In general, initial erosion rates would be increased depending on soil exposure, slope steepness, and precipitation patterns. Soil losses on undisturbed lands in northwestern Montana are commonly less than 2 tons/acre/year, but under all action alternatives, soil loss rates would likely exceed 2 tons/acre/year on all disturbed areas until vegetation was established and roads were chip-sealed or graveled. Following reclamation, soil losses of less than 2 tons/acre/year are typically needed for successful revegetation. Past silvicultural/soil rehabilitation activities have displayed that vegetation ground cover is expected to be present within a 3 to 5 year timeframe following reclamation activities, and longer on steep slopes and road cuts, especially on south- and west facing slopes.

Losses of soil at disturbances, such as Ramsey and Libby Plant Sites, Libby Adit Site, Little Cherry Creek and Poorman Tailings Impoundment sites, and soil stockpiles would be captured by sediment control BMPs. Soil losses at soil stockpiles also would be controlled by installing berms around the stockpiles.

Soil losses would occur at cut-and-fill slopes at the plant sites, at mine and transmission line access roads, and at staging areas. Fill slopes would be particularly susceptible to failure, and difficult to revegetate, and cut-and-fill slope raveling (movement of dry soils) may be difficult to control in some locations. Construction of new roads and upgrading of existing roads would cross areas where soils have a severe erosion risk, high sediment delivery potential to enter waterways, and potential for slope failure. Some roads would be reclaimed as work progressed, so surface erosion would be limited. Road-building in steep terrain typically results in accelerated erosion and sedimentation (Megahan and Kidd 1972). Increases in erosion would be highest within the first 2 years, and, after 2 years, the sediment generated by mitigation roads would be negligible (see section 3.13.4, *Water Quality*). Because precipitation is high in the area, cut-and-fill slopes would be immediately stabilized to reduce potential erosion. Road cut-and-fill slopes and other disturbances along roads would be seeded, fertilized, and stabilized with hydromulch, netting, or by other methods as soon as final grades are achieved after construction to minimize erosion and to avoid crusting of the soil surface. Soil crusting would reduce seed establishment and water infiltration and result in more runoff and erosion.

Following construction of the transmission line, interim reclamation (removal of drainage obstructions at road crossings, replacement of soil where it was removed and reseeding) would be used on transmission line access roads placed into intermittent stored service to stabilize the surface and reduce erosion. Erosion from the transportation system is analyzed in section 3.13.4, *Water Quality*. All new roads would be decommissioned at the end of operations when no longer needed and most other existing roads would be reclaimed to preoperational conditions. Some roads would be covered by the tailings impoundment in all mine action alternatives.

Unprotected road surfaces would be susceptible to erosion. Access roads operational for mine life would be chip-sealed or graveled, which would reduce potential erosion, and BMPs would be used to control drainage from road surfaces. For existing roads needing upgrading, sediment controls would be upgraded/installed and appropriate BMPs would be implemented, which would result in long-term reduction of soil loss from existing road corridors. For more information with regard to expected sediment reductions from road BMPs, see section 3.13.4, *Water Quality*.

BMPs have been proven to be an effective tool in limiting non-point source pollution (DNRC 2010, KNF 2002b, Logan 2001). If properly constructed and located, BMPs keep soil erosion to a minimum, capture sediment before it enters waterways, and protect water quality by controlling the flow of surface water over exposed areas. Additionally, BMPs help to keep soil particles in place and thereby provides a better plant growth medium for reclamation. The proper use of BMPs prevents, any eroded soil from making its way to the watershed outlet, where it would create problems downstream; the loss of surface soil also would make achieving revegetation goals more problematic. Erosion would occur during reclamation activities when salvaged soils are spread on recontoured surfaces. Areas reclaimed using direct-hauled soils (a reclamation technique whereby soil is stripped from an undisturbed area and immediately placed on a disturbed area that has been prepared for reclamation), such as road cut-and-fill slopes and in places at the Little Cherry Creek and Poorman Tailings Impoundment sites, would have less potential for erosion than areas reclaimed with stored soil. This is because protective vegetation would establish more quickly because direct-haul soils, as opposed to stored soils, are still biologically active and retain a higher level of favorable physical and chemical characteristics than soils stored for prolonged periods (U.S. Congress, Office of Technology Assessment 1986). Only a small, undetermined percentage of the total volume proposed for salvage would be direct-handled because of the timing difference between construction and reclamation.

Wind erosion of exposed soil also would contribute to soil losses. To minimize soil wind erosion, MMC would use standard BMPs, such as periodic watering of unpaved roads and disturbed surfaces, and use of mulch and tackifiers on exposed surfaces until vegetation was established.

Soil losses would occur under all action alternatives, and even with erosion and sediment control BMPs, some soil losses are expected but would be minimized. Soil losses generally would be long-term within all disturbed areas, because erosion rates would remain elevated after reclamation until the vegetation ground cover approaches predisturbance levels in about 3 to 5 years. South- and west-facing cut slopes may require more than 5 years for the vegetation ground cover to reach predisturbance levels without soil amendments. Once vegetation was well established, soil losses are expected to be similar to pre-mine rates.

3.19.4.1.2 Soil Physical, Biological, and Chemical Characteristics

Soil characteristics that would be impacted by all action alternatives would include potential changes in soil physical and chemical properties, and biological activity, including nutrient levels. Soil structure would be altered by handling, salvage, and storage operations. Changes in chemical properties such as heavy metal concentrations and soil pH may also occur at the mine facilities. These changes to the soil characteristics are discussed below.

Physical Characteristics

Changes in physical properties of the soils due to handling, salvage, and storage would result in the alteration of the natural soil profile that has developed since the last major soil disturbing event such as glacial activity, volcanic ash deposition, or flooding. This would be an unavoidable impact of salvaging and replacing soils. Some of these areas have been logged in the past, which disturbed the surface soil profile but not to the extent that mining disturbance would. Changes in soil structure, compaction (destruction of pore space continuity and soil structure), and loss of organic matter due to mixing and storage would occur. Soils salvaged and replaced in a single lift would alter the natural soil profile due to mixing of soil horizons, which would be a long-term impact. Two-lift salvage and replacement is proposed in the tailings impoundment areas that would limit some of the mixing across soil horizons, but the impacts would still be long term. The establishment of vegetation, root systems, and physical processes, such as freezing and thawing, and wetting and drying, would restart the soil-building processes and help rebuild the natural soil profile. Where the soil profile would be altered, it would require many years for soil productivity to return to pre-mine conditions. Compaction from heavy equipment would adversely affect soil plant relations due to decreased soil water-holding capacity, loss of aeration and pore space, and increased soil bulk density (Sharma and Doll 1996). Organic-rich soils, such as surface soils, and fine-grained matrix soils that have a large volume of rock fragments, are less affected, depending on the overall soil composition (Greacen and Sands 1980).

Volcanic ash-influenced soils in northwest Montana have lower initial bulk densities than soils derived from other sources. When disturbed during activities that use heavy equipment (such as logging), these soils are particularly susceptible to compaction (Page-Dumroese 1993; Geist *et al*. 2008; McDaniel and Wilson 2007), and compaction can persist for decades (Johnson *et al*. 2007; Parker *et al*. 2007). Soils with significant amounts of coarse fragments are less susceptible to compaction from heavy equipment (Luckow and Guldin 2004), and soils with higher clay contents (greater than 20 percent clay) are more effective at ameliorating the effects of compaction, due to freezing and thawing and shrink-swell actions than ash soils, which are particularly low in clay content (Parket *et al*. 2007). Volcanic ash soils within the analysis area generally have clay contents less than 23 percent (Western Resource Development Corp. 1989b, 1989c). Additionally, studies have not explored the behavior of ash-influenced soils under prolonged storage in deep piles; therefore, it is not possible to quantify the potential resistance to compaction of these soils.

Fine-textured glaciolacustrine subsoils are susceptible to compaction during the soil salvage process and have lower inherent infiltration and permeability. Non-glaciolacustrine soils in the area would not be as susceptible to this compaction because they often have greater sand and rock fragment contents.

To reduce compaction, severely compacted areas, such as roads, soil stockpile sites, and facility sites, would be ripped before soil placement, and seedbeds would be disked and harrowed before seeding. Soil compaction would be short-term in all disturbed areas with these mitigation measures, and following reclamation, compaction in re-spread soils that are ripped would be similar to pre-mine soils.

Biological Activities

Biological changes would occur in salvaged soils. Since most disturbances would not be reclaimed until the end of operations, most salvaged soils would be stockpiled for 15 years or more. Soils salvaged along transmission line roads would be re-spread within a year. Prolonged storage decreases or eliminates populations of important soil microorganisms (Abdul-Kareem and McRae 1984), such as bacteria, fungi, and algae, which are essential in soil nutrient cycling. In addition, some favorable components normally found in native soils are lost through decomposition during storage. These components include seeds of native plants, rhizomes (underground stems), and other plant parts capable of producing new plants. Replenishment of soil microorganisms would occur with interim revegetation of soil stockpiles but would be limited to the surface (the top 6 to 8 inches) of the stockpile. Most stockpiled soil would have reduced biological activity.

Mycorrhizae (important structures that develop when certain fungi and plant roots form a mutually beneficial relationship) are also eliminated in soil stored for prolonged periods. Mycorrhizae serve as highly efficient extensions of plant root systems, especially for woody species. These associations are important to consider in maximizing plant establishment and productivity because most plants depend on mycorrhizae for adequate growth and survival (Mallock *et al.* 1980). This is especially true in nutrient deficient soils. All of the salvaged soils are considered to have low fertility. Mycorrhizae are particularly important to plant phosphorus nutrition (Bolan 1991) and water uptake (Augé 2004). Thus, the association of mycorrhizae with plants in the study area is especially critical because plant-available phosphorus is expected to be low.

Chemical Characteristics

Aluminum, iron, and manganese are found in native forested soils in the area. These common metals are released by the weathering of soil parent materials, even in non-mineralized areas. They can become concentrated in a particular soil horizon by various soil-formation processes. Although typically not available to plants at neutral pH values, if soil surveys indicate soil pH is around 5.0, the agencies would require soil metal testing to identify possible naturally occurring concentrations of these and other metals. Soil samples tested had pH values from 4.3 to 7.5, with values between 5.0 and 6.0 being the most common. Samples with low pH were generally from the Little Cherry Creek and Poorman Tailings Impoundment sites, but soils with low pH potentially occur at all proposed disturbance areas. Soils having pH conditions below 5 are not proposed to be salvaged. Aluminum in particular may be slightly elevated in volcanic ash-rich loess. Elevated aluminum levels are common in the widespread volcanic forested soils of northwest Montana (McDaniel and Wilson 2007; Page-Dumroese *et al*. 2007), and native vegetation likely has adapted to the ambient soil chemistry.

Heavy metals often associated with mineralized zones, such as lead and copper could hinder plant growth. None of the rock types tested during exploration and past mining operations exhibited highly elevated leachable metal concentrations, which are metals that would become soluble in soil water (see section 3.9.4, *Environmental Geochemistry* for detailed discussion of leachable metals). Preliminary testing shows tailings materials and some of the mine waste rock would have low levels of leachable metals and no net acid generation potential. Considering these results, the mine waste materials would have limited adverse chemical impacts on re-spread soil or on plants whose roots may grow into these materials in the lower part of the rooting zone. MMC would test waste rock and tailings before soil redistribution to reconfirm these results.

3.19.4.1.3 Reclamation Success

Recognition of inherent soil properties and design of salvage programs to retain favorable properties can enhance reclamation success. Soil characteristics important to consider for analyzing impacts and assessing soil salvageability and suitability for reclamation include:

- Depth and horizon (developed soil layer) sequence
- Texture (relative proportion of sand-, silt-, and clay-sized particles)
- Coarse fragment content (size, amount, and shape (rounded or angular))
- Erodibility
- Organic matter content
- Reaction (refers to the acidity or alkalinity of the soil solution and is expressed as pH ranging from 1 to 13, where 1 is the most acidic, 7 is neutral, and 13 is most alkaline or basic)
- Slope steepness; and location and extent of rock outcrop and talus

Soil Salvage and Handling

The potential for reclamation success of disturbed lands is greatly improved when soil is salvaged and later replaced in two or more lifts to provide a suitable growth medium for plants (Montana State University 2004). MMC would salvage and replace soils on most disturbed areas, except where slopes are too steep, at soil stockpile areas, and where soils are too rocky. The primary limitations that affect soil suitability for salvage and reclamation at the site include high rock content and steep slopes, and to a lesser extent, soil texture, soil pH, and a high water table. Salvage may be limited for soils with a volume of more than 50 percent rock fragments (larger than 1/16 inch diameter) or with large rocks (greater than 2 feet in diameter). Soils with up to 60 percent rock fragments would be salvaged in some areas to provide erosion protection on the steep embankment of the Little Cherry Creek and Poorman Tailings Impoundment sites. Salvage would not be required and not be conducted on slopes exceeding 2:1 (50 percent) because of worker safety considerations. Other reclamation limitations at the site include soils with high clay content and pH levels below 5, which increase the potential for metal mobility out of soils.

Soil Amendments

Reclamation success can be enhanced on particular sites by use of soil amendments. Use of mulches and tackifiers can limit soil loss until seedlings can establish. Alkaline amendments can be added to acid soils to raise the pH. Wood based organic amendments can be added to the surface soil to increase organic matter contents, reduce compaction, reduce crusting, increase soil fertility, lower bulk density, and potentially enhance establishment of a fungal based mycorrhizae community that would enhance the establishment and growth of woody plant species. MMC has only proposed the use of mulches to reduce soil erosion.

Revegetation

The main factors relating to revegetation include scheduling of final revegetation, species selection, planting plans, and establishing success criteria to achieve long-term plant cover and density objectives. These factors determine the speed and success of reclaiming the disturbed lands to comparable stability and utility.

MMC would not implement final reclamation for most disturbances until the post-operational phase (after 15 to 20 years). Final reclamation would be done on some sites during the predevelopment period (1 to 3 years). These areas would include the Little Cherry Creek Diversion Channel (Alternatives 2 and 4), cut-and-fill slopes at plant sites, portal patio faces, and the Bear Creek access road north of the proposed Little Cherry Creek Tailings Impoundment. Disturbances reclaimed during operations would include some temporary access roads. Interim reclamation, (replacing soil where it was removed and reseeding) would occur on transmission line access roads placed into intermittent stored service. All other disturbances would be reclaimed after operations cease.

3.19.4.2 Soil Loss

3.19.4.2.1 Alternative 1 – No Mine

Under Alternative 1, the Montanore Project would not be developed. Soil resource impacts would be limited in comparison to the other alternatives. Soil loss due to erosion would be restricted to existing exploration-related or baseline data collection disturbances. All existing soil disturbances by MMC would be reclaimed in accordance with existing laws and permits. Erosion and sedimentation would occur at existing rates along NFS road #278 and other existing roads. Soil erosion losses due to rainfall, runoff, and wind would continue at natural rates at other locations in the analysis area.

3.19.4.2.2 Alternative 2 – MMC's Proposed Mine

Soil losses would occur during construction of access roads and facilities, at soil stockpiles, and when soils are salvaged and re-spread. Table 165 presents a comparison of the likely disturbances in which soil would be salvaged and salvageable soil volumes of mine facilities for each alternative. The disturbance acres in Table 165 do not include proposed soil stockpiles and existing roads because no soil would be salvaged from these areas. Soil would be salvaged from only small portions of LAD Areas such as roads and ponds. The Libby Adit Site is an existing disturbance area, and soil has already been salvaged and stockpiled at the site, so it is not included in Table 165.

Alternative 2 - Soil Losses from Construction of Facilities and Roads

Construction of mine related facilities and roads would result in soil disturbance and a loss of soil productivity on about 2,081 acres (Table 165). Much of the facility disturbances would be covered with structures, such as buildings, or other material, such as tailings and waste rock.

New roads, upgrading existing roads, and pipeline corridors would disturb 153 acres. Unprotected road surfaces would be susceptible to erosion. For access roads operational for mine life, MMC would chip-seal or gravel road surfaces, which would reduce potential erosion, and BMPs would be used to control drainage from road surfaces. For existing roads needing upgrading, MMC proposes to upgrade/install sediment controls and implement appropriate BMPs, which in the long run, would reduce total soil loss (see section 3.13.4, *Water Quality*).

Table 165. Comparison of Disturbances from Soil Salvage and Salvageable Soil for Alternatives.

Disturbance	Units	Alternative 2 – MMC's Proposed Mine	Alternative 3 – Agency Mitigated Poorman Impoundment Alternative	Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Areas of culvert replacement and/or extension and bridge construction at Ramsey Creek and Poorman Creek would be subject to erosion until stabilized. Short-term increases in sedimentation may occur as a result.

MMC proposed a 10,800-foot Little Cherry Creek Diversion Channel around the tailings impoundment that would flow into Libby Creek. The Diversion Channel would consist of two main sections: an upper engineered channel (designed for the 6-hour Probable Maximum Flood flow and the riprapped channel sides for the 100-year flood flows), and two down gradient existing natural drainage channels that flow toward Libby Creek (Figure 8). These two existing channels, referred two as Drainage 10 and Drainage 5, would both receive flow from the Upper Diversion Channel, which would reduce channel impacts that can occur during peak flow events. The existing channels would not be large enough to handle the expected flow volumes; these channels would undergo channel adjustments until they stabilized. These adjustments would include bank erosion, channel scouring, and sloughing of bank material, which would contribute sediments to Libby Creek.

MMC would construct some bioengineering and structural features based on need and access in the two unnamed tributary channels to reduce flow velocities, minimize erosion in the unnamed tributaries, minimize sedimentation to Libby Creek, and create fish habitat. In addition, MMC would evaluate potential locations for creating wetlands and ponds in low gradient areas to capture and retain most of the sediments generated from the unnamed tributaries and minimize sedimentation to Libby Creek. If wetlands or ponds were not constructed to retain mobilized sediments on the Libby Creek floodplain, the additional input of sediments to Libby Creek may cause channel aggradation, which may result in bank erosion due to channel widening. Bank erosion in the unnamed tributaries and possibly sedimentation to Libby Creek would continue until the tributaries adjusted to the increased flow volumes (see section 3.6, *Aquatic Life and Fisheries*). If substantial erosion occurred once the diversion channel was operational, additional erosion control structures would be constructed as needed.

Once the tailings impoundment was reclaimed, there would be a slight increase in flow to Bear Creek from runoff from the impoundment surface. This runoff would flow to Bear Creek via a diversion ditch. The ditch would be riprapped to minimize erosion and sedimentation in Bear Creek. A small, rockfill check dam would be located just beyond the northwest end of the reclaimed impoundment. If necessary, sediment would be removed from the pond. The check dam would be designed for the 100-year flood event. Short-term erosion in the ditch and subsequent sedimentation in Bear Creek would likely occur during construction of the ditch and check dam. With the additional flow, especially after large runoff events, there could be minor adjustments to the Bear Creek channel resulting in minor scouring and bank erosion.

Alternative 2 - Soil Losses at Soil Stockpiles

All soil stockpiles would be susceptible to erosion. Soil stockpiles would be constructed with 40 percent side slopes and 33 percent sloping ramps where possible. MMC proposes to stabilize stockpiles when they reach their design capacity, and seed during the first appropriate season following stockpiling. This would leave exposed soil on steep slopes for potentially prolonged periods. If left exposed and unprotected for more than a couple of months, regardless of other characteristics, large amounts of soil may erode. To minimize sedimentation to floodplains, wetlands and streams, MMC proposes to locate soil stockpiles on gentle slopes away from drainages, install berms around stockpiles, and construct sediment traps downslope of soil stockpiles where necessary.

Apart from erosion resulting from steep slopes and exposure, each stockpile would have a different potential for erodibility. Each stockpile includes soils from adjacent or nearby salvage areas, thus the nature of each stockpile would be different in terms of soil texture and rock content. For example, soils at the Ramsey Plant Site would be salvaged in one lift and would be composed of predominately silt loam with lesser amounts of gravelly silt loam and very gravelly silt loam. Due to the high silt content and only some soils having high gravel content, these stored soils would have a moderate to high erodibility potential. Some soils at the Little Cherry Creek Tailings Impoundment Site would be salvaged in two lifts and stored separately. The surface lift, which includes the more suitable soil, would be comprised of fine-textured volcanic ash, silt loam, gravelly silt loam, and gravelly loam. First-lift stockpiles would have moderate to high erodibility potential due to the high silt content and low rock fragment content. The second lift would be composed of gravelly to very gravelly loam and clay loam. Second-lift stockpiles would have moderate erodibility potential due to higher rock fragment content and less silt.

For new roads that are to be operational for mine life, MMC proposes to stockpile soils along the entire corridor. Most of these soils have a volcanic ash surface layer and have a moderate to high erodibility potential due to the high silt content and low rock fragment content. Stockpiling soils along entire corridors would increase the surface area of exposed soil and thereby result in more soil losses than if salvaged soils were concentrated in only a few stockpiles in clearings or areas of recent timber harvest immediately adjacent to new roads.

Alternative 2 - Soil Losses from Soil Salvage and Replacement

Soil losses during salvage and replacement activities could affect the volume of soil estimated for salvage, particularly at LAD Areas and at the Libby Adit Site where salvageable soil was limited (soils have already been salvaged and stockpiled at the Libby Adit Site). This in turn would affect proposed redistribution depths at LAD Areas and at the Libby Adit Site and could potentially adversely affect reclamation success. MMC reports that previous reclaimed disturbances with less than 18 inches of re-spread soil at the Libby Adit Site have demonstrated viable vegetation cover, and MMC proposes to re-spread 18 inches of soil at disturbances in LAD Areas requiring soil replacement.

MMC proposes to store all first-lift soils salvaged from the Little Cherry Creek Tailings Impoundment Site together, including surface soils having no or few rock fragments and high erosion potential, such as glaciolacustrine soils, with surface soils having a large amount of rock fragments. This could result in having highly erosive soils on the steep surface of the embankment of the impoundment and lead to excessive erosion of surface soils exposing less fertile subsoil and affecting long-term reclamation success on the impoundment embankment.

MMC proposes to salvage some clay-rich glaciolacustrine subsoils (>40 percent clay) at the Little Cherry Creek Tailings Impoundment Site. This soil type is poorly suited as a plant growth medium due to shrinking and swelling, surface crusting, low water infiltration, slow permeability, and high erodibility potential. If this clay-rich material were used as final re-spread surface soil, plant re-establishment would be impeded and erosion would likely increase, especially on the tailings embankment.

In summary, MMC's proposed measures to control runoff and sedimentation and combined with some of the native surface soil and subsoil characteristics, such as rock fragment content, would help reduce erosion rates. If glaciolacustrine soils were used as surface soil on the impoundment, soil losses could affect reclamation success in the long term especially on the embankment of the impoundment for reasons discussed previously. Until vegetation ground cover reached predisturbance levels, anticipated to be in about 3 to 5 years in most areas, erosion rates would be higher than before disturbance. Soil losses are not expected to affect reclamation success at other disturbance areas, because sufficient soil material exists to meet MMC's proposed reclamation plan, with the possible exception at LAD Areas and at the Libby Adit Site where salvageable soil was limited.

3.19.4.2.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Alternative 3 would result in a loss of soil productivity on 1,441 acres where soil would be salvaged. It would meet soil quality standards as one of the long-term reclamation goals. In addition to the fewer disturbed acres than Alternative 2, Alternative 3 also would provide additional mitigation measures that would result in less erosion and less sedimentation to Libby Creek and its tributaries. These additional measures are described below.

On all soil stockpiles, interim seeding and mulching would be conducted incrementally as the stockpiles are being constructed and as soon as possible, regardless of season, rather than waiting until the first appropriate season after they reach design capacity. This would reduce erosion potential and potentially reduce sedimentation to drainageways.

For new roads that are to be operational for mine life, salvaged soils would be stockpiled in clearings or in areas of recent timber harvest immediately adjacent to new roads or in other nearby soil stockpiles rather than stockpiling along the entire road corridor. Consolidating soil stockpiles would improve management and control soil losses along road corridors and minimize sedimentation to nearby waterways. MMC would develop and implement a Road Management Plan addressing all roads used in the alternative. Successful implementation of the plan would ensure that erosion and sediment delivery from roads would be minimized.

A Little Cherry Creek Diversion Channel would not be needed under Alternative 3. Elimination of the Diversion Channel would reduce short-term erosion in the unnamed tributaries and sedimentation to Libby Creek. The potential long-term effects of channel aggradation and bank erosion from channel widening in Libby Creek and the potential for sedimentation and bank erosion in Bear Creek also would be eliminated. Once the tailings impoundment was reclaimed, there would be a 40 to 70 percent increase in average annual flows in Little Cherry Creek as runoff from the impoundment surface would be directed to Little Cherry Creek. This increase in flow would cause some short-term scouring and bank sloughing in Little Cherry Creek closer to the impoundment and some sedimentation farther downstream.

For soil salvage at the Poorman Tailings Impoundment Site, rocky soil would be segregated from non-rocky soil. Soil would be replaced in two lifts 24 inches thick on the embankment and impoundment surface. Rocky subsoil would be used as re-spread subsoil (15 inches thick) over the tailings embankment, and rocky surface soil would be used as the upper 9 inches of re-spread soil on the embankment. This would minimize erosion potential on the embankment. The non-rocky surface soil would be used as the upper 9 inches of re-spread soil on the rest of the impoundment on slopes less than 8 percent. The clay-rich subsoil of glaciolacustrine soils salvaged from the impoundment area would be stockpiled separately from other second-lift soils and used, along with other salvaged soil, as re-spread subsoil (15 inches thick) on top of the tailings impoundment. It could also be used to cover any sandy or gravelly soils exposed during impoundment site stripping and borrow excavation operations to minimize infiltration of water from the tailings impoundment or from the Seepage Collection Pond. An average of 24 inches of surface soils and 12 inches of subsoils at all wetlands would be excavated and used at wetland mitigation sites (see section 2.5.7.1, *Jurisdictional Wetlands and Other Waters of the U.S.*).

With the modifications to control erosion under Alternative 3, soil losses within the disturbed areas would be less and not as severe as under Alternative 2, and sedimentation to waterways would be less for Alternative 3 than for Alternative 2 (section 3.19.4.2.2, *Alternative 2 – MMC's Proposed Mine*). Because 640 fewer acres would be disturbed in Alternative 3 than in Alternative 2, Alternative 3 would have less soil loss.

3.19.4.2.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Alternative 4 would salvage soils from 1,791 acres (Table 165). Alternative 4 would provide the same additional mitigation measures as Alternative 3, which would result in less erosion and less sedimentation to Libby Creek and its affected tributaries. MMC would develop and implement a Road Management Plan addressing all roads used in the alternative. Successful implementation of the plan would ensure that erosion and sediment delivery from roads would be minimized.

Under Alternative 4, a Little Cherry Creek Diversion Channel would be built and would consist of two main sections: an upper engineered channel and a constructed lower channel to Libby Creek using an existing drainage channel (Drainage 10 proposed in Alternative 2). The engineered channel would be the same as the engineered channel under Alternative 2 and would be designed for the 6-hour Probable Maximum Flood. It would flow into a constructed channel that would be designed to be geomorphologically stable and to handle the 2-year flow event. The natural-designed channel would have similar channel pattern, dimensions, profile, and bed material as similar-sized channels in the analysis area (see design elements listed in section 2.6.3.2, *Modified Little Cherry Creek Tailings Impoundment*). A floodplain would be constructed along the channel to allow passage of the 100-year flow.

Significant erosion and sedimentation should not occur because construction of the channel would be done in dry conditions. The majority of sediment generated would occur during initial channel flush and subsequent high flow and rainfall events. In the event of heavy precipitation during construction of the channel, significant erosion may occur. Natural and biodegradable materials and vegetation would be used along stream banks and on the floodplain to minimize erosion, stabilize the stream channel and floodplain, and minimize sedimentation to the lower channel and Libby Creek. Long-term monitoring and maintenance would be required, if necessary, until the lead agencies determine that the channel was stabilized. Even with these mitigation measures, the constructed natural-designed channel would be subject to erosion and sedimentation during construction and until vegetation stabilizes the stream banks and floodplain. Short-term increases in sedimentation to the lower channel and Libby Creek would likely occur as a result.

Following reclamation of the impoundment, the constructed channel would undergo an additional period of channel adjustment when runoff from the impoundment surface was directed to the Diversion Channel. The increase in flow would be about 50 percent higher than during operations, and would lead to new channel adjustments. This would likely cause short-term increases in sedimentation in the lower channel and Libby Creek.

For soil salvage at the Alternative 4 Little Cherry Creek Tailings Impoundment, rocky surface soil would be segregated from non-rocky surface soil. Like Alternative 3, rocky subsoil would be used as re-spread subsoil (15 inches thick) over the tailings embankment, and rocky surface soil would be used as the upper 9 inches of re-spread soil on the embankment. This would minimize erosion potential on the embankment. Non-rocky surface soil would be used as the upper 9 inches of re-spread soil on the rest of the impoundment on slopes less than 8 percent. Also like Alternative 3, clay-rich subsoil of glaciolacustrine soils salvaged from the impoundment area would be stockpiled separately from other second-lift soils and would be used, along with other salvaged soil, as re-spread subsoil (15 inches thick) on top of the tailings impoundment. It could also be used to cover any sandy or gravelly soils exposed during impoundment site stripping and borrow excavation operations to minimize infiltration of water from the tailings or from the Seepage Collection Pond, or to line the channel foundation for the Little Cherry Creek Diversion Channel.

With the modifications to control erosion under Alternative 4, soil losses within the disturbed areas would be less and not as severe as Alternative 2 and sedimentation to waterways would be less for Alternative 4 than for Alternative 2 (section 3.19.4.2.2*, Alternative 2 – MMC's Proposed Mine*). Compared to Alternative 3, Alternative 4 would disturb more acres creating greater potential for soils loss, and Alternative 4 would require the construction of the Little Cherry Creek Diversion Channel, which would increase the risk of channel erosion and sedimentation to waterways.

3.19.4.2.5 Transmission Line Alternatives

Alternative A – No Transmission Line

Under Alternative A, the transmission line, Sedlak Park Substation, and loop line for the Montanore Project would not be built. Soil erosion losses due to water and wind would continue at natural rates. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that do not affect National Forest System lands. Effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

Alternative B – North Miller Creek Alternative

MMC's proposed North Miller Creek transmission line corridor would be 16.4 miles long and would require 108 structures. This alternative is slightly longer than the lead agencies' alternatives in part because it ends at the substation at the Ramsey Plant Site where the lead agencies' alternatives end at the substation at the Libby Plant Site about 1.5 miles to the east. The centerline of the transmission line of the North Miller Creek Alternative would cross more steep areas (7.4 miles), more soils with a severe erosion hazard (6.7 miles), and more soils with high sediment delivery (5.1 miles) than the other three alternatives. The disturbance associated with structure placement would increase erosion until vegetation ground cover around the structure locations reached predisturbance vegetation ground cover levels. MMC did not specify the type of logging that would be used. For analysis purposes, the lead agencies assumed all logging would be completed conventionally without the use of a helicopter. Disturbance associated with logging operations would increase soil erosion.

The primary surface disturbance from transmission line construction would be construction of new access roads. The total disturbance for access roads, which would be either new roads or existing closed roads requiring upgrades, would be greater under this alternative (30.9 acres) than the other alternatives. The access roads would disturb 8.9 acres of soil having severe erosion risk, 6.3 acres of soil having high sediment delivery potential to waterways, 13.3 acres of soil having potential for slope failure, and 16.5 acres of slopes greater than 30 percent (Table 166). Disturbances on steeper slopes are generally more difficult to reclaim and require more mitigation measures than on shallower slopes. The majority of soils having severe erosion risks along access roads occur along Libby and Miller creeks and Fisher River. Most soils with high sediment delivery potential disturbed by access roads occur along Ramsey, Libby, and Miller creeks and Fisher River. Most soils having potential for slope failure occur along Ramsey Creek, just east of Libby Creek, and near Fisher River. Access roads on slopes exceeding 30 percent primarily occur along Ramsey Creek, between Libby and Miller creeks, north of Miller Creek, and locations east of the Fisher River (Figure 84).

Table 166. Comparison of Physical Characteristics and Erosion Risks for Transmission Line Alternatives.

Criteria	Units	Alternative B – North Miller Creek	Alternative C-R – Modified North Miller Creek	Alternative D-R – Miller Creek	Alternative E-R – West Fisher Creek
Length of Transmission Line	Miles	16.4	13.1	13.7	15.1
Total road disturbance	Miles	10.2	3.1	5.1	3.9
	Acres	30.9	9.4	15.5	11.7
Severe erosion risk					
Centerline only	Miles	6.7	1.8	1.3	3.4
New roads + closed roads with high upgrade requirements	Acres	8.9	2.4	1.8	2.3
High sediment delivery					
Centerline only	Miles	5.1	0.5	0.5	0.5
New roads + closed roads with high upgrade requirements	Acres	6.3	0.6	0.6	0.6
Slope failure					
Centerline only	Miles	9.3	6.8	7.5	9.4
New roads + closed roads with high upgrade requirements	Acres	13.3	4.7	6.4	6.4
Slopes > 30 percent					
Centerline only	Miles	7.4	7.2	6.4	4.7
New roads + closed roads with high upgrade requirements	Acres	16.5	4.4	7.9	2.5

Source: GIS analysis by ERO Resources Corp. using vegetation mapping in USDA Forest Service and Natural Resources Conservation Service 1995.

Sediment controls and BMPs would be implemented on new and upgraded roads during construction of the transmission line to minimize erosion, sediment delivery to waterways, and slope failure. All access roads, after construction of the transmission line but during the life of the project, would be closed and placed into intermittent stored service and reclaimed with interim reclamation designed to stabilize the surface. This reclamation would include removal of drainage obstructions at road crossings, reseeding the road surface, and where soil had been salvaged from new roads, the road surface would be covered with soil and then reseeded.

After the transmission line was removed, all newly constructed roads on National Forest System lands would be decommissioned. They would be recontoured to match existing topography, obliterating the road prism, and reseeded. Where culverts were removed, stream banks would be recontoured and reseeded. Final closure status of new access roads on private lands would be based on the landowner’s discretion. With sediment controls, BMPs and short duration of exposed soil, there would be no severe reclamation constraints, no significant adverse impacts to the soil resources, and the soil losses along access roads would likely be minor until vegetation was re-established in most areas after 3 to 5 years. Vegetation re-establishment on steep areas, particularly on south- and west-facing slopes, could take longer.

In all action transmission line alternatives, the BPA would construct and operate the Sedlak Park Substation and loop line. The Sedlak Park Substation and loop line site is on a flat terrace of the Pleasant Valley Fisher River. The site is underlain by glaciolacustrine soils, which have severe erosion risk and are prone to slope failure. The BPA would prepare and implement a SWPPP during substation and loop line construction to minimize water erosion. The substation site would have a stormwater containment system. After the transmission line was removed, the substation site would be decommissioned and the site reclaimed. Soil losses at the Sedlak Park Substation and loop line site would be minimal.

Alternative C-R – Modified North Miller Creek Alternative

The Modified North Miller Creek Alternative would be 13.1 miles long, the shortest of all alternatives, require 81 structures, and end at the substation at the Libby Plant Site, which is about 1.5 miles east of the proposed substation at the Ramsey Plant Site under Alternative B. The centerline would cross 7.2 miles of steep slopes, 6.8 miles of slopes prone to failure, 1.8 miles of soils with severe erosion risk, and 0.5 miles of soils with high sediment delivery. The disturbance associated with structure placement would increase erosion until vegetation ground cover around the structure locations reached predisturbance vegetation ground cover levels. MMC would use a helicopter to harvest timber at selected locations, reducing the need for access roads (Figure 44). Conventional logging techniques would be used in other areas. Helicopter logging would result in less soil erosion than conventional logging used in Alternative B.

New access roads and closed roads with high upgrade requirements would be needed for transmission line installation and would create 9.4 acres of disturbance, the fewest of all alternatives and about 22 acres fewer than Alternative B. These roads would disturb 2.4 acres of soils having severe erosion risk, 4.7 acres of soil that have potential for slope failure, the fewest of all alternatives, and 4.4 acres of slopes greater than 30 percent. Alternative C-R (and Alternatives D-R and E-R) would affect few soils with high sediment delivery potential to waterways (0.6 acres). Most soils having severe erosion risks along access roads occur along Libby Creek in the extreme western portion of the transmission line, along Miller and West Fisher creeks, and along Fisher River. Soils having high sediment delivery potential along access roads occur only in two places, along Libby Creek and at the northeast end along the Fisher River. Most soils having potential for slope failure along access roads occur just east of Libby Creek, portions between Miller and West Fisher creeks, and east of Fisher River. Access roads on slopes exceeding 30 percent occur primarily between Libby and Miller creeks, north of Miller Creek, much of the area between Miller and West Fisher creeks, and along portions east of Fisher River (Figure 84). MMC would develop and implement a Road Management Plan addressing all roads used in the alternative. Successful implementation of the plan would help minimize erosion and sediment delivery from roads.

Sediment controls and BMPs would be implemented on new roads to minimize erosion, sediment delivery to waterways, and slope failure. As with Alternative B, new access roads on National Forest System lands would be placed into intermittent stored service after line construction was completed. Intermittent stored service roads would be closed to traffic and would be treated, which would include at a minimum removing drainage obstructions, replacing salvaged soil, seeding, and installing cross drains, so they would cause little resource risk if maintenance were not performed on them during the operation period of the mine and before their future need. Intermittent stored service is described in section 2.9.4.2*, Access Road Construction and Use*.

After removal of the transmission line, transmission line roads on National Forest Systems lands would be decommissioned. The road prism would be obliterated, all watercourses would be restored, and the road prism would be revegetated. Road decommissioning is described in section 2.9.4.2*, Access Road Construction and Use*. Unlike Alternative B, for Alternative C-R, the surface soil that had been in place on access roads for the life of the transmission line would be salvaged, the road prism obliterated, and then the surface soil replaced. The surface soil that had been in place for the life of the transmission line would have higher nutrient levels, higher organic matter content, and greater microbial activity than the underlying soil, and it would be a seed source for the native plants that had established over the life of the transmission line. This would shorten the amount of time for vegetation to re-establish, which would minimize the amount of time bare soil was exposed to erosive forces.

Newly constructed roads on Plum Creek lands would be gated after construction and managed as proposed by MMC in Alternative B. As with Alternative B, final closure status of new access roads on private lands would be based on the landowner's discretion. With fewer acres of disturbance and the shorter amount of time soil was exposed, impacts probably would be lower than those on Alternative B. With sediment controls, BMPs and short duration of exposed soil, there would be no severe reclamation constraints, no significant adverse impacts to the soil resources are expected, and the soil losses along access roads would likely be minor until vegetation was re-established in about 3 to 5 years for most areas. Vegetation re-establishment on steep areas, particularly on south- and west-facing slopes, could take longer.

Alternative D-R – Miller Creek Alternative

The Miller Creek Alternative would be 13.7 miles long, require 92 structures, and end at the substation at the Libby Plant Site. This alternative would cross the least amount of soil having severe erosion risk (1.3 miles). The centerline of this alternative would cross more soils that have potential of slope failure than Alternative C-R, but would cross fewer steep slopes than Alternative C-R. The Miller Creek Alternative would disturb fewer soils having slope failure potential and steep slopes than Alternative B (Table 166). Some areas would be logged using a helicopter, resulting in disturbances and erosion similar to Alternative C-R.

New access roads and closed roads with high upgrade requirements would create 15.5 acres of disturbance (about 16 fewer acres than Alternative B), and disturb 7.9 acres of slopes that exceed 30 percent, 0.6 acres of soils with high sediment delivery potential to waterways, and 6.4 acres of soil that have potential for slope failure. Access roads for this alternative would cross the fewest acres of soil having severe erosion risk (1.8 acres). Most soils having severe erosion risks along access roads occur along Libby Creek in the extreme western portion of the transmission line, along West Fisher Creek and Fisher River. The majority of soils with high sediment delivery potential along access roads occur only along Libby Creek and at the northeast end along the Fisher River. Most soils having potential for slope failure along access roads occur southeast of Libby Creek near Howard Lake, portions between Miller and West Fisher creeks, and east of Fisher River (Figure 84). Other effects and measures to control soil losses associated with the transmission line and corresponding access roads would be the same as Alternative C-R.

Alternative E-R – West Fisher Creek Alternative

The West Fisher Creek Alternative would be 15.1 miles long, require 103 structures, and end at the substation at the Libby Plant Site. The centerline would cross 4.7 miles of slopes greater than 30 percent, less than all other alternatives, and would cross 9.4 miles of soils that have potential of slope failure, which is essentially the same as Alternative B and more than Alternatives C-R and D-R. The centerline of Alternative E-R would cross fewer miles of soils that have severe erosion risk (3.4 miles) than Alternative B but more miles than Alternatives C-R and D-R. Some areas would be logged using a helicopter, resulting in disturbances and erosion similar to Alternative C-R.

New access roads and closed roads with high upgrade requirements would create 11.7 acres of disturbance (about 19 fewer acres than Alternative B), and would disturb 2.3 acres of soils having severe erosion risks, which occur primarily along Libby and West Fisher creeks and Fisher River. This alternative would affect 6.4 acres of soils with a potential for slope failure, which occur southeast of Libby Creek near Howard Lake, portions north of West Fisher Creek, and east of Fisher River. Access roads would cross 2.5 acres having slopes greater than 30 percent, which is less than any other alternative and occur primarily southeast of Howard Lake, along portions north of West Fisher Creek and along portions east of Fisher River (Figure 84). Other effects and measures to control soil losses associated with the transmission line and corresponding access roads would the same as Alternative C-R.

3.19.4.3 Soil Physical, Biological, and Chemical Characteristics

Soil characteristics that would be impacted by action Alternatives 2, 3, and 4 and by the transmission line action alternatives include changes in soil physical properties, biological activity, and nutrient levels. The likelihood of changes in chemical properties such as changes in heavy metal concentrations and soil pH are also discussed.

3.19.4.3.1 Alternative 1 – No Mine

Under Alternative 1, the Montanore Project would not be developed. Soil changes in physical and chemical properties, biological activities, and nutrient levels would be limited to any existing exploration-related or baseline collection disturbances. All existing exploration-related or baseline collection disturbances by MMC would be reclaimed in accordance with existing laws and permits. In all other areas, soil changes in physical and chemical properties, biological activities, and nutrient levels would continue at natural rates.

3.19.4.3.2 Alternative 2 – MMC Proposed Mine

Alternative 2 - Physical Characteristics

Single lift soil salvage and replacement would alter the natural soil profile by mixing soil horizons that developed over the past 10,000 years. MMC would use the single lift salvage and replacement method at the Ramsey Plant Site, the Libby Adit Site, the LAD Areas, and access roads. The Little Cherry Creek Tailings Impoundment Site would have soils salvaged and replaced in two lifts. This would limit impacts from mixing soil horizons but the loss of soil development and the length of time to re-establish a new soil profile would still take a long time. At other disturbance sites where soils would be salvaged using a two-lift method, the soils would be replaced using a single-lift method. There would be a long-term impact on the soil profile at these sites. Over time, natural processes would rebuild a new soil profile that may or may not resemble the predisturbance condition. The loss of soil development and the time needed to redevelop a new soil profile would be an unavoidable impact of soil disturbance.

To minimize soil compaction, MMC would rip compacted areas before redistribution of soil. Areas expected to be ripped include the adit portal areas, roads, soil stockpile sites, the dam face of Little Cherry Creek Tailings Impoundment, and facility areas. Ripping also would eliminate potential slippage at layer contacts and promote root growth. Following soil redistribution, the seedbed would be disked and harrowed on slopes 33 percent or less, which would minimize compaction of the seedbed. These practices would tend to offset compaction on many reclaimed sites. Some areas, such as road fills and as much as possible at the tailings impoundment site, would receive direct-hauled soil. If seeded immediately, and provided that soils are handled when dry, compaction would be minimal. MMC has not committed to handle soils when dry. If soils were wet when handled, some compaction is expected, especially on slopes greater than 33 percent because the seedbed on these slopes would not be disked and harrowed. The establishment of vegetation, root systems, rodent activity, and physical processes such as freezing and thawing, and wetting and drying would decrease soil compaction. In time, effects related to soil compaction of respread soils would be reduced.

Alternative 2 - Biological Activities

The loss of organic matter and mycorrhizae in soils stockpiled for prolonged periods could lower plant species diversity (Strohmayer 1999). If mycorrhizae-inoculated trees and shrubs species were readily available, MMC would use these species and would use stock raised in containers where the soil medium has been inoculated with mycorrhizae, if it were available. The loss of organic matter and mycorrhizae would be a long-term impact, and if mycorrhizae inoculation were not completed, the long-term survival and growth of woody species, in particular, may be reduced. In time, mycorrhizae would invade reclaimed sites from adjacent undisturbed areas, and species diversity would eventually increase, but not to pre-mine levels as discussed in section 3.22.1.4*, Environmental Consequences*.

Alternative 2 - Soil Nutrients

As is typical of many forest soils, nutrient levels are low to very low partially due to low soil pH. During soil storage, these levels would only decrease as organic matter and biological activity decreased and precipitation leached nutrients through the stockpiles. Soil stockpiles would contain organic debris, such as residual coniferous forest slash that was acidic, that could decrease soil pH as the material weathers.

Soils formed in volcanic ash often fix phosphorus in a form unavailable for plant uptake (McDaniel and Wilson 2007). Organic matter in the upper few inches of native soils acts as a reservoir for phosphorus. Plant-available phosphorus is released by microbial decomposition within and directly below the forest litter layer. Replaced soils would lack organic matter, as explained above; therefore, surface applications of soluble phosphorus fertilizer at the time or before seeding, as proposed by MMC, may be of little value. MMC has proposed to apply organic matter in the form of straw mulch, which has little nutrient value, and wood mulch may be used if straw mulch proved to be ineffective for successful reclamation. MMC would test areas with poor plant germination and/or growth to determine causes of unsuccessful revegetation and then take corrective actions. This would help offset organic matter and/or phosphorous deficiencies.

MMC proposes to salvage equal volumes of first-lift soils and second-lift soils at borrow sites C and D. In doing so, MMC may not necessarily segregate the most suitable soil that would be used as the upper 9 inches of respread soil. Mixing surface soil with subsoil would reduce organic matter content in first-lift replaced soils, which would affect availability of essential nutrients. This may also affect the success of plant re-establishment unless additional organic matter was applied to these areas. The same would be true with using single-lift soil salvage and replacement method at the sites mentioned above. This would mix soil horizons and thereby reduce organic matter content in first-lift replaced soil at these sites.

To minimize these impacts, MMC would complete soil tests before seeding to determine the appropriate fertilizer rates required for successful reclamation. Fertilizer and mulch would be applied on respread soils at the time and before seeding, and nitrogen fertilizer would be broadcasted over the soil surface after seeding early in the subsequent growing season. MMC's proposed soil testing program to identify fertilizer and other possible soil amendment needs, and taking corrective actions in areas of poor plant growth would help offset nutrient deficiencies in respread soils in the short term, and then when vegetation became re-established and soil building processes began on reclaimed areas, nutrient levels would eventually reach predisturbance levels.

Alternative 2 - Chemical Characteristics

Seeps from soil stockpiles in forested regions in other parts of Montana have indicated elevated levels of iron and manganese (USDA Forest Service and DEQ 2001). The levels of tannic acids increase and soil pH is reduced due to the breakdown of coniferous forest vegetation in the stockpiles. Low pH and increased levels of iron and manganese can result in complex nutrient deficiency and/or phytotoxicity problems in many plant species (Kabata-Pendias and Pendias 1984). Reduced plant growth and/or mortality would slow or severely impair reclamation. Applications of composted organic matter have helped improve plant growth on reclaimed sites with affected soils (Environmental Protection Agency 2007d). MMC has proposed to apply straw mulch but would test areas with poor plant germination and/or growth to determine causes of unsuccessful revegetation and then take corrective actions.

3.19.4.3.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

To better preserve the natural soil profile, double-lift soil salvage and replacement would be used at most disturbances, including the Poorman Tailings Impoundment Site, Libby Plant Site, and along access roads that already have existing cleared areas to store additional soil or that are near other soil stockpile areas. Single-lift salvage and replacement would be used along road segments that do not have existing cleared areas large enough to store two lifts of soil or that are not near other soil stockpile areas. Where single-lift salvage and replacement would be used for access roads, the soil profile on reclaimed access roads would be more severely impacted and require more time to rebuild than at areas reclaimed using double-lift soil replacement method. Over time, natural processes would rebuild a new soil profile that may or may not resemble the predisturbance condition. The loss of soil development and the time needed to redevelop a new soil profile would be an unavoidable impact of soil disturbance.

To minimize compaction, all salvaged soils would be handled at the low moisture content, and all disturbed areas that have been re-soiled and are to be seeded would be scarified to a depth of 6 to 12 inches before seeding to minimize compaction and improve seed establishment. The entire tailings impoundment and severely compacted areas, such as roads, soil stockpile sites, and facility sites would be ripped up to 18 inches deep with dozer ripping teeth before soil replacement to reduce compaction and break up surface crust to facilitate water infiltration and enhance rooting depth. Soil compaction would be short-term in all disturbed areas with these mitigation measures, and following reclamation compaction in re-spread soils that are ripped would be similar to pre-mine soils.

Where redistributed soils cover non-native material, such as the entire Poorman Tailings Impoundment and if any waste rock storage areas remained at the end of mining, an average of 24 inches of soil would be replaced in two lifts to provide sufficient rooting depth. Other reclaimed sites in Montana have shown that 24 inches of re-spread soil provides sufficient rooting depth (Plantenberg, pers. comm. 2006).

To promote the rebuilding of mycorrhizae in areas where trees are to be planted in respread soils that have been stored for prolonged periods, either an agencies-approved wood-based mulch would be incorporated into the upper 4 inches of re-spread soil (Plantenberg, pers. comm. 2006), and/or inoculated tree-planting stock with the appropriate mycorrhizal fungi would be used, or mycorrhizal fungi would be incorporated into the soil as pellets during seeding.

As mentioned earlier, organic matter in the upper few inches of native soils acts as a reservoir for phosphorus, and replaced soils that were stored for prolonged periods would lack organic matter. To enhance phosphorus and other nutrient levels and to increase organic matter levels, the upper 4 inches of re-spread soil would be amended with an agencies-approved wood-based organic amendment before planting. This also would stimulate the development of fungal based mycorrhizae in the new soil.

Because of the observed metal leaching and low pH problems from soil stockpiles containing large amounts of coniferous vegetation at other mine sites in Montana, most coniferous forest debris would be removed before soil salvage. This also would minimize soil nutrient losses, because low pH conditions can result in complex nutrient deficiency and/or phytotoxicity problems.

The additional mitigation measures of Alternative 3 for limiting the total loss of the natural soil profile, soil compaction, loss of soil biological activity, and reduction of nutrient levels would reduce the severity of these impacts when compared to Alternative 2. In addition, these measures would enhance reclamation success more than Alternative 2. Based on extensive reclamation experience of mined lands, the agencies anticipate that the mitigation measures would be highly effective.

3.19.4.3.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Modifications for Alternative 4 would be similar to the modifications in Alternative 3. The effects of these modifications would be similar as well. The difference would be the tailings impoundment would be at the same location as for Alternative 2, and would disturb 30 more acres than the tailings impoundment in Alternative 3, increasing the potential for soil loss. Other effects from the tailings impoundment would be the same as Alternative 3, because both Alternatives 3 and 4 would require 24 inches of soil to be re-spread over the entire impoundment including the top of the impoundment.

As with Alternative 3, to better preserve the natural soil profile, double-lift soil salvage and replacement would be used at most disturbances, including the same disturbances as Alternative 3 but also at the Little Cherry Creek Tailings Impoundment Site and the Little Cherry Creek Diversion Channel. Single-lift salvage and replacement would be used for some roads segments as Alternative 3.

3.19.4.3.5 Transmission Line Alternatives

Alternative A – No Transmission Line

In Alternative A, the transmission line, Sedlak Park Substation, and loop line for the Montanore Project would not be built. Soil changes in physical and chemical properties, biological activities, and nutrient levels would continue at natural rates. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that do not affect National Forest System lands. Effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

Alternative B – North Miller Creek Alternative

Changes in physical properties of the soils due to handling under the North Miller Creek Alternative, which includes the Sedlak Park Substation and loop line, would be similar to those listed in section 3.19.4.1, *Effects Common to All Action Alternatives*. The natural soil profile would be altered, there would be a loss of soil pore space (an increase in compaction), and a loss of organic matter due to mixing. Most of these changes in the soil (except alteration of the soil profile) would be short-term, in part because all access roads would have soil replaced (if soil were removed) and would be reseeded immediately following transmission line completion. Additionally, protective vegetation on road surfaces would establish more quickly because soils stockpiled for short durations are still biologically active and retain a higher level of favorable physical and chemical characteristics than soils stored for prolonged periods. To minimize soil compaction, MMC would rip access roads, if necessary, when no longer needed. Following soil replacement, the seedbed would be disked and harrowed, which would minimize compaction of the seedbed.

Soils would be salvaged in a single lift for new access roads and for some existing roads altering the natural soil profile that developed over thousands of years. The establishment of vegetation, root systems, and physical processes, such as freezing and thawing, and wetting and drying, would help rebuild a new soil profile, but this would be a long-term impact and would require a long time.

Alternative C-R – Modified North Miller Creek Alternative

Changes in physical, chemical and biological properties of the soils due to handling from road construction and interim reclamation under the Modified North Miller Creek Alternative would be similar to those listed under the North Miller Creek Alternative.

Because with final reclamation, the surface soil that had been in place for the life of the transmission line would be salvaged and then replaced after the road prism was obliterated, changes in physical and biological properties of the soils due to handling under the Modified North Miller Creek Alternative would be less than under the North Miller Creek Alternative. The natural soil profile would still be altered but not as severely, there would still be a loss of soil pore space (an increase in compaction), the loss of organic matter would be reduced due to less mixing of the soil, and the soil biological activity would be less affected. This would shorten the time to re-establish vegetation and for successful reclamation. The better soil handling methods and the fewer acres of disturbance under the Modified North Miller Creek Alternative (Table 166) would reduce the effects of impacts when compared to the effects in the North Miller Creek Alternative.

Alternative D-R – Miller Creek Alternative

Changes in physical, chemical, and biological properties of the soils due to handling in the Miller Creek Alternative would be similar to Alternative C-R.

Alternative E-R – West Fisher Creek Alternative

Changes in physical, chemical, and biological properties of the soils due to handling in the West Fisher Creek Alternative would be similar to Alternative C-R.

3.19.4.4 Reclamation Success

Factors important to successful reclamation include soil salvage and handling, vegetation removal and disposition, revegetation, and success criteria.

3.19.4.4.1 Alternative 1 – No Mine

Under Alternative 1, the Montanore Project would not be developed. Reclamation would be limited to any existing exploration-related or baseline collection disturbances. All existing exploration-related or baseline collection disturbances by MMC would be reclaimed in accordance with existing laws and permits.

3.19.4.4.2 Alternative 2 – MMI Proposed Mine

MMC's reclamation goal is to establish a post-mining environment compatible with existing and proposed land uses and consistent with the KFP. Specific goals of reclamation serve a number of purposes as described in MMC's reclamation plan (MMC 2007).

Alternative 2 - Soil Salvage and Handling

Table 165 presents a comparison of the likely disturbances in which soil would be salvaged and salvageable soil volumes of mine facilities for each alternative. The table shows salvageable volumes for first lift and second lift soil. Even though MMC proposes to use double-lift salvage at the Little Cherry Creek Diversion Channel and other potential disturbances within the Little Cherry Creek Tailings Impoundment, they do not propose to use a double-lift replacement at these sites. These second-lift soils would only be used on the tailings impoundment.

MMC proposes to redistribute 24 inches of soil on the embankment of the Little Cherry Creek Tailings Impoundment using a double-lift salvage and replacement method. Replaced soil depths on other disturbed areas would be 18 inches including the top of the tailings impoundment. The double-lift salvage and replacement would provide enhanced soil physical and chemical properties in the reclaimed surface soil layer. First-lift soils would have more favorable conditions for revegetation establishment, such as higher organic matter content, higher nutrient levels, and better soil structure, which has higher porosity that facilitates plant root development. This practice attempts to salvage and replace some of the natural soil profile characteristics that developed on the site since the last major climatic change.

Total soil disturbance of the Little Cherry Creek Tailings Impoundment would be 620 acres (Table 165). Soils in the impoundment area, in part, would be replaced based on soil erodibility and slope steepness. For example, the least erodible colluvial/glacial soils having the greatest rock fragment content would be used as subsoil (15 inches thick) on the embankment of the impoundment to minimize erosion potential. Rock fragments reduce the erodibility of soils by anchoring the surface. First-lift soils, would consist of both rocky and non-rocky surface soils, and would be used as surface soil over the entire impoundment including the embankment. Soil replacement on the embankment would be in two lifts; 15 inches of rocky subsoil on bottom followed by 9 inches of surface soil on top. Over the rest of the impoundment MMC proposes soil replacement in two lifts; 9 inches of second-lift soil followed by 9 inches of first-lift soil. If MMC did not use rocky soil for the upper 9 inches on the tailings embankment, erosion of the surface may occur and expose the less fertile subsoil. If this happened, successful reclamation on the tailings embankment may not be achieved.

The tailings material on the top of the impoundment would be composed of sands and silts that would not be phytotoxic (lethal or damaging to plants). It is likely that this material, especially the silts, would become hard and compacted upon drying. Without scarification or deep ripping before soil placement, this fine tailings material could become an effective barrier to root penetration and could affect long-term establishment of deep rooted plants such as trees and shrubs. Because tailings on the dam face would be coarser and because MMC proposes to deep rip the dam face before soil placement, a physical rooting barrier on the dam face would not be an issue.

Material below salvageable soil depths from borrow areas that occur outside the footprint of the Little Cherry Creek Tailings Impoundment would be used for construction on portions of the Saddle Dams, Starter Dam, Seepage Collection Dam, or toe dike. These borrow areas would create about 419 acres of disturbance (Table 165), and have an average of 14 inches of salvageable soils. About 282 acres of soil in this area have not been mapped at a site-specific intensive level. In addition, about 44 acres of soil in other disturbances in the impoundment area and 139 acres of road disturbance requiring soil salvage and replacement have not been mapped at an intensive level. Not mapping the soils at an intensive level before salvage may result in not salvaging all suitable soil and/or salvaging some unsuitable soils, such as soils having low pH conditions. If unsuitable soils were used as re-spread soils, plant establishment may be adversely affected.

The total disturbance for the Ramsey Plant Site would be 49 acres. Salvageable soil depths at the site are about 24 inches, of which MMC proposes to salvage 18 inches in one lift. The total disturbances for the Little Cherry Creek Diversion Channel would be 40 acres. Salvageable soil depths along the Diversion Channel are about 13 inches, of which MMC proposes to salvage about 9 inches in one lift. The total disturbance from roads would be about 153 acres, on which MMC proposes to salvage and replace soils in one lift. Not utilizing the double-lift salvage and replacement method would mix the relatively organic-rich and nutrient-rich surface soil layer with the poorer quality subsoil layer and place more unproductive soil on the surface. Plant establishment may be reduced and could take longer for reclamation success to be achieved.

The total soil disturbance for the LAD Areas 1 and 2 would be 31 acres. The disturbed areas at the LAD Areas would include ponds, embankments, ditches, soil stockpile areas, and access roads. LAD Area 1 also would include a waste rock disposal area. LAD Area disturbances would require soil salvage (except soil stockpile areas) and reclamation. The larger areas used for land application and disposal would require only selective thinning of trees, access road construction, and little soil removal. Salvageable soil depths at LAD Areas average about 9 inches, but MMC would respread 18 inches of soil over the disturbances at LAD Areas. Some soil likely would be hauled from elsewhere to compensate for the shortage of salvaged soil at LAD Areas. Impacts to reclaimed disturbances at the LAD Areas would be the same as other areas not having a double-lift soil replacement.

Many of the impacts resulting from soil salvage and handling would be moderate in the long term for comparable stability and utility determinations. Long-term effects could occur on the embankment of the Little Cherry Creek Tailings Impoundment if surface erosion occurred and exposed subsoil. Long-term effects could occur on the top of the impoundment if the surface were not ripped to break up any rooting barriers, at areas where unsuitable soils may be used, and at areas where the double-lift soil replacement were not used.

Alternative 2 - Vegetation Removal and Disposition

MMC has not proposed any special plan to deal with vegetation removal and disposition other than harvesting trees and burning slash. This may result in the loss of a source of native plant materials, less organic debris that could be used for BMPs, and loss of potential non-coniferous organic enrichment in stockpiled soils. Opportunities to enhance reclamation success could be lost. If too much coniferous forest debris were left on the soil and salvaged with the soil, soil pH in the stockpiles could be reduced.

Alternative 2 - Revegetation and Success Criteria

MMC has developed two final seeding/planting mixes to accommodate the differences in disturbance areas and an interim seed mix (MMC 2007). These mixes would be dominated by native species, but some introduced species would be included. Introduced species may hinder colonization of native species and could spread off the reclaimed areas. Before reclamation, MMC would submit seed mix information to the lead agencies, so that the agencies would have an opportunity to adjust seed mixes as appropriate for site conditions and to meet any KFP changes. If the agencies required removal of introduced species from seed mixes, the adverse long-term effects that introduced plant species would have on reclaimed sites and surrounding areas would be reduced.

Trees and shrubs would be planted on steeper slopes of the Little Cherry Creek Tailings Impoundment throughout the project life as areas were reclaimed, on cut-and-fill slopes at the Ramsey Plant Site, the Libby Adit Site, and portions of LAD Areas. MMC would plant trees and shrubs at the end of operations on all other disturbances including the top of the impoundment and waste rock dumps, if present at the end of operations. Trees and shrubs would not be planted on the Rock Lake Ventilation Adit, soil stockpile sites, portal patios, and along road corridors. In these areas, reforestation would occur by natural regeneration. This approach would increase the time needed to achieve a natural looking setting, to provide screening, and to achieve important wildlife habitat components. A well-established grass cover in these areas likely would retard the establishment of volunteer trees. It may take up to 20 years for settling to stop and to complete redistributing soil on top of the tailings impoundment. Delaying tree and shrub planting on top of the tailings impoundment would delay development of wildlife habitat.

MMC's proposed 18 inches of re-spread soil on top of the tailings impoundment, rather than 24 inches, and not ripping the tailings surface to break up surface crusting before soil placement may hinder tree root growth and overall growth rates likely would decline. Root systems would eventually penetrate the tailings, but the mass of roots likely would be concentrated in the upper 18 inches of soil, resulting in slower growing and possible stunted trees over time, and trees would likely be more prone to wind throw.

MMC proposes to plant 435 trees per acre; based on a survival rate of 65 percent, the final anticipated stocking rate after 15 years would be about 283 trees per acre. Shrubs would be planted at a rate of 200 stems per acre. The proposed planting rates may not meet overall wildlife or density recommendations by the agencies, and would require many years before stem densities on reclaimed sites have similar densities to that of surrounding landscapes.

The proposed planting plan includes the spacing of trees and shrubs to be continuous on slopes in strips alternating with strips that would be seeded with an herbaceous understory mixture, or would be spaced in randomly placed groupings on level to gently sloping areas. Planting in alternating strips would not match surrounding landscape features, would not meet visual quality objectives and may allow for noxious weed establishment along the planting strips.

If feasible, MMC would consider collecting seed or plant materials onsite to ensure the genetic adaptation of planting stock to local environmental conditions, and inoculating soils used for planting trees and shrubs with mycorrhizae. This would enhance the chances for survival, growth, and reproduction, which are necessary for long-term successful reclamation.

In summary, MMC's revegetation plan may affect long-term reclamation success and results. Potential effects include the introduction of non-native plant species, extended establishment time for trees and shrubs in some areas, and reduced woody plant densities. The potential for the spread of noxious weeds may also increase.

Part of MMC's reclamation goals include revegetation success criteria, which are anticipated to be met after a 3 to 5 year monitoring period. These success criteria include:

- Total plant cover would be at least 80 percent of the total cover of a specific control site or would meet a 70 percent total cover basis with at least 60 percent consisting of a live plant community
- There would be no more than three acceptable plant species that dominate a site based on the seed mix or natural plant community in the area, and noxious weeds would not be more than 10 percent of the plant community
- There would be no rills and gullies greater than 6 inches deep and/or wide

If any success criterion were not met after 3 years of monitoring, MMC would access the problems and correct any deficiencies of seed types, techniques or methods and take corrective measures. This process would continue until all revegetation goals were met.

3.19.4.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Short- and long-term reclamation objectives would remain the same as for Alternative 2. Modifications and their effects on soil salvage and handling, vegetation removal and disposition, revegetation, and success criteria are discussed below.

Alternative 3 - Soil Salvage and Handling

Soil would be salvaged and replaced in all disturbed areas, with the exception of soil stockpile areas, slopes greater than 50 percent, and cut slopes in consolidated material. Where redistributed soils cover non-native material such as the entire Poorman Tailings Impoundment and waste rock piles (if remaining at end of mine life), the replaced soil depth would average 24 inches using two lifts. This would produce soil depths more comparable to pre-mine conditions and would increase the likelihood of successful revegetation. Research generally has shown that replacement of 24 inches of soil over suitable mine waste rock would produce maximum plant productivity (Coppinger *et al.* 1993). At all other disturbances, soil replacement depths would average 18 inches. Double lift salvage and replacement also would occur at all disturbances requiring soil salvage and replacement except for some road segments and at the Upper Libby Adit, which would have 1 acre of disturbance and there would be no suitable second-lift soil. Double-lift soil salvage and replacement would be used along access roads that already have cleared areas to store additional soil or that are near other soil stockpile areas. To minimize disturbance size and tree removal, single-lift salvage and replacement would be used along road segments that do not have existing cleared areas large enough to store two lifts of soil or that are not near other soil stockpile areas. The lead agencies would identify road areas where double-lift soil salvage and replacement would be appropriate. Reclamation would be enhanced by salvaging some soils to greater depths to provide sufficient salvageable soil volumes to achieve the soil replacement goals for all potential disturbances.

About 47 acres of soil at Borrow Area 2 and the potential rock borrow area, all soils at the Libby Plant Site (106 acres), about 105 acres of soil at other potential disturbances within the Poorman Tailings Impoundment Site, and about 107 acres of soil along roads have not been mapped at an intensive, site-specific level. Before any soils would be salvaged, intensive soil surveys would be conducted in these areas to ensure the most suitable soil and necessary volumes of soil were salvaged.

Other modifications of soil salvage and handling have been discussed in section 2.5.2.5.2, *Soil Salvage and Handling Plan*. These other modifications along with thicker soil replacement depths at most disturbances, and the most suitable soil and maximum volumes would be salvaged, would help to ensure both short-term and long-term successful revegetation.

Alternative 3 - Vegetation Removal and Disposition

A Vegetation Removal and Disposition Plan that would evaluate the potential uses of vegetation removed from areas to be disturbed and would describe disposition and storage plans during mine life would be prepared. This plan would result in the maximum use of native plant materials and organic debris to enhance reclamation success. Where possible, slash of non-coniferous forest debris from timber-clearing would be salvaged and chipped to be used as mulch or as an additive to stored surface soil stockpiles. Because of the observed metal leaching from soil stockpiles containing large amounts of coniferous vegetation at other mine sites in Montana, coniferous forest debris would be removed before soil removal.

Alternative 3 - Revegetation and Success Criteria

Revegetation and success criteria would be developed for all reclaimed areas. These criteria would help ensure revegetation was successful over both the short and long term, that noxious weeds did not exceed unacceptable levels, and desired cover densities were achieved and sustained in the long term.

Alternative 3 would include more stringent requirements for mine reclamation than Alternative 2 (Table 167). A 20-year revegetation monitoring period after reseeding would be required, if necessary, under Alternative 3 to better ensure that revegetation requirements have been achieved. A longer monitoring period also would provide additional time to take corrective measures if revegetation goals had not been met.

Table 167. Mine Reclamation Requirements by Alternative.

Reclamation Requirement	Alternative 2 MMC's Proposed Mine	Alternative 3 Agency Mitigated Poorman Tailings Impoundment Alternative	Alternative 4 Agency Mitigated Little Cherry Creek Tailings Impoundment Alternative
Seed Mix	Native and introduced species; interim and permanent seed mixes	Native; permanent seed mix only	Same as Alternative 3
Tree/Shrub Density After 15 Years	283 trees/acre (assumes a 65% survival rate of 435 trees/acre planted) Unspecified (200 shrubs/acre planted)	400 trees/acre 200 shrubs/acre	Same as Alternative 3
Noxious Weeds	No more than 10% noxious weeds	Less than or equal to the cover of noxious weed species present on agency-approved disturbed/reclaimed control sites in the area	Same as Alternative 3
Total Cover	60% live vegetation cover or 70% of disturbed/reclaimed control site total cover	80% of disturbed/ reclaimed control site total cover	Same as Alternative 3
Monitoring Plan	3 consecutive years of revegetation success	20 years	Same as Alternative 3
Total Acres of Vegetation Disturbance	2,582	1,539	1,886

†Priority weeds described in KFP; see Table 183.

The reclamation requirements for Alternative 3 would increase the minimum vegetation cover required after reclamation compared to Alternative 2. A total of 80 percent cover would be the goal compared to 70 percent for Alternative 2. Alternative 3 would require a sufficient planting of trees and shrubs to achieve 400 trees and 200 shrubs per acre living after 15 years, except in wetlands and meadows. Compared to Alternative 2, this would increase woody plant density. Woody plant densities under Alternative 3 would better match surrounding landscape features and would meet wildlife and density recommendations provided by the agencies.

All seed mixes would be revised so that mixes would be composed of species native to northwestern Montana (if commercially available) instead of a seed mix that that includes introduced species as proposed in Alternative 2. This would reduce the spread of aggressive introduced species both in reclaimed sites and nearby sites, and enhance the conditions for re-establishment of native species.

Rather than planting trees and shrubs along strips as proposed in Alternative 2, trees and shrubs would be planted by hand in random patterns to better resemble natural surroundings. Planting in random patterns along with increased woody plant densities, would return reclaimed sites to more natural conditions in less time than under Alternative 2.

Surface soil would be amended before seeding with an agencies-approved wood-based organic amendment to raise soil organic matter levels to a minimum of 1 percent by volume. This would increase water holding capacity of the soil, enhance nutrient levels, stimulate biological activity in the soil, and thereby, help ensure successful revegetation.

3.19.4.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Short- and long-term reclamation objectives would remain the same as for Alternative 2. Modifications to soil salvage and handling, vegetation removal and disposition, revegetation, success criteria, and monitoring are the same as described above in Alternative 3, with a few modifications described below.

Alternative 4 - Soil Salvage and Handling

In Alternative 4, as under Alternative 3, where redistributed soils cover non-native material such as the entire Little Cherry Creek Tailings Impoundment Site and waste rock piles (if remaining at end of mine life), the replaced soil depth would average 24 inches using two lifts. Sufficient salvageable soil volumes are available to achieve the soil replacement goals for all potential disturbances.

The soils at the Libby Plant Site (same as Alternative 3), about 24 acres of soils in the southwestern portion of the Borrow Area outside the impoundment footprint, 19 acres of soil at other potential disturbances within the Cherry Creek Impoundment Site and about 106 acres of soil along access roads have not been mapped at an intensive, site-specific level. Before any soils would be salvaged, MMC would conduct intensive soil surveys in these areas to ensure that the most suitable soil and necessary volumes of soil were salvaged. In addition, a two-lift soil salvage and replacement method would be conducted at the Libby Plant Site, along some portions of access roads, at other disturbances within the Little Cherry Creek Impoundment Site, and at the Little Cherry Creek Diversion Channel.

Other modifications of soil salvage and handling incorporated into Alternatives 3 and 4 have been discussed in section 2.5.2.5.2, *Soil Salvage and Handling Plan*. These modifications along with the modifications mentioned above would help ensure successful long-term revegetation.

3.19.4.4.5 Alternative A – No Transmission Line

In Alternative A, the transmission line, Sedlak Park Substation and loop line for the Montanore Project would not be built. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that do not affect National Forest System lands. Effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

3.19.4.4.6 Alternative B – MMC Proposed North Miller Creek Alternative

Alternative B - Soil Salvage and Handling

Soils would be salvaged and replaced using a single-lift method and would be handled in the same manner as explained in Alternative 2. Not using the double-lift salvage and replacement method would mix relatively organic-rich and nutrient-rich surface soil with poorer quality subsoil and place more unproductive soil on the surface, which could delay successful reclamation. Where soils are salvaged from new access roads, the soil would be stored adjacent to the disturbance.

Roads opened or constructed for transmission line access would be closed after the transmission line had been built. The road surfaces would be reseeded as an interim reclamation activity designed to stabilize the surface. Where soil had been salvaged from new roads, the road surface would be covered with soil and then reseeded. The new road prism would remain until the transmission line was removed at the end of operations. After the transmission line was removed, all newly constructed roads would be recontoured to match the existing topography, obliterating the road prism, and reseeded.

Alternative B - Vegetation Removal and Disposition

MMC has not proposed any special plan to deal with vegetation removal and disposition other than harvesting trees and burning slash. This could result in the loss of a source of native plant materials, less organic debris for BMPs such as slash filter windrows or use of chipped non-coniferous wood debris, and loss of potential organic enrichment in stockpiled soils. Opportunities to enhance reclamation success could be lost.

Alternative B - Revegetation and Success Criteria

At the end of the mine life and following redistribution of soil, all access roads would be reseeded with the same seed mixes as in Alternative 2. MMC has not proposed to plant trees on reclaimed access roads and other disturbances where trees were removed such as line stringing and tensioning sites, slash burn piles, and construction pads. MMC's revegetation plan for the transmission line access roads would have the same long-term effects as under Alternative 2, including the spread of introduced plant species, the additional years required for trees and shrubs to become established on reclaimed road surfaces and other disturbance sites, and the potential for spreading noxious weeds. The revegetation, success criteria, and monitoring would be the same as under Alternative 2.

3.19.4.4.7 Alternative C-R – Modified North Miller Creek Alternative

Alternative C-R - Soil Salvage and Handling

Under the Modified North Miller Creek Alternative, soil salvage and handling would be the same as under Alternative B for road construction and for interim reclamation. The effects on soils also would be the same.

For final decommissioning of access roads, the surface soil that had been in place on access roads for the life of the transmission line would be salvaged, the road prism obliterated, and then the surface soil replaced. The surface soil that had been in place for the life of the transmission line would have higher nutrient levels, higher organic matter content, and greater microbial activity than the underlying soil, and it would be a seed source for the native plants that had established over the life of the transmission line. This would shorten the amount of time for vegetation to re-establish. The depth of surface soil salvage would be determined by the lead agencies before final reclamation. Other soil handling methods would be in the same manner as under Alternative B.

At the end of operations, mycorrhizae and the agencies-approved wood-based mulch would be incorporated into the upper 4 inches of soil to raise the soil organic matter levels to 1 percent by volume in the recontoured road surfaces. This would shorten the amount of time to successfully reclaim all transmission line access roads.

In Alternatives C-R, D-R, and E-R, wooden structures would be used (wooden monopoles would be used for a 0.5-mile segment of Alternative E-R). Wooden poles would be treated to reduce decay; a typical preservative contains sodium, copper and petroleum compounds. Typically, soil contamination surrounding a pole is minor and does not extend beyond 10 to 24 inches away from the pole (Arisi *et al*. 2006; Brooks 1998).

Alternative C-R - Vegetation Removal and Disposition

As described in section 2.5.2.5.2*, Vegetation Removal and Disposition Plan*, a Vegetation Removal and Disposition Plan would be prepared that evaluates the potential uses of vegetation removed from areas to be disturbed. This plan would result in the maximum use of native plant materials and organic debris for BMPs to enhance reclamation success.

Alternative C-R - Revegetation and Success Criteria

Trees would be planted in all areas where trees were removed for the construction of the transmission line including access roads and other disturbances such as line stringing and tensioning sites, slash burn piles, and construction pads. Trees would be planted at a density that at the end of 5 years the approximate stand density of the adjacent forest would be attained at maturity. This standard would not apply to roads placed in intermittent stored service, but would apply when the roads would be decommissioned after the transmission line was restored. Planting trees in disturbances would require less time for trees to become establish, would better match surrounding landscape features, and would meet wildlife and density recommendations provided by the agencies.

All seed mixes for both interim reclamation and final reclamation would be revised so that mixes would be composed of species native to northwestern Montana and not contain introduced species. This would reduce the spread of aggressive introduced species both in reclaimed sites and nearby sites, and enhance the conditions for re-establishment of native species. The monitoring plan, revegetation, and success criteria (except tree and shrub densities) would be the same as under Alternative 3.

3.19.4.4.8 Alternative D-R – Miller Creek Alternative

For the Miller Creek Alternative, effects and modifications to soil salvage and handling, vegetation removal and disposition, revegetation, and success criteria would be the same as for Alternative C-R.

3.19.4.4.9 Alternative E-R – West Fisher Creek Alternative

For the West Fisher Creek Alternative effects and modifications to soil salvage and handling, vegetation removal and disposition, revegetation, and success criteria would be the same as for Alternative C-R.

3.19.4.4.10 Effectiveness of Agencies' Mitigation Measures

MMC's implementation of the agencies' numerous mitigations regarding soil salvage, stockpiling, and replacement, vegetation removal and disposition, and revegetation procedures described in Chapter 2 would be effective in ensuring all lands disturbed by mining were reclaimed to a post-mine land use and to comparable stability and utility. Salvage of 3 feet of wetland soils for use at wetland mitigation sites would be effective in providing suitable soils for wetland creation.

3.19.4.5 Cumulative Effects

Cumulative effects include the combination of direct and indirect effects from past, present, and reasonably foreseeable activities. Direct, indirect, and cumulative effects on soils are measured within each activity area. Existing system roads and designated landings on National Forest transportation system are considered dedicated lands and are not part of the soils cumulative effects. The highly variable nature of soil productivity requires site-specific analyses to adequately address reclamation needs. Assessments of cumulative effects on soil productivity are retained at the site specific boundary scale. In contrast, soil processes such as erosion regime and hydrologic functions occur at a watershed scale.

Past actions, particularly road construction, timber harvest, and mining activities have increased erosion rates in comparison to undisturbed areas in the analysis area. As vegetation in timber harvest areas return to pre-harvest conditions, erosion rates have and would continue to decrease. Cumulative effects on soils from other current and foreseeable actions would be associated primarily with potential soil loss from erosion and loss of soil productivity. Other regional current and foreseeable actions that would affect soil resources include timber harvest, mineral exploration, and new road construction. These actions would potentially occur on both public and private lands. There may also be abandoned mine waste cleanup on public and private lands, and continued commercial and residential development on private lands. The primary soil disturbance of many of these activities would be from road construction and soil removal. These actions would result in an increase in erosion and sedimentation within the Libby Creek and Fisher River watersheds, and a loss of soil productivity in areas where soil was removed, stored for prolonged periods, and then replaced.

The KNF requires the implementation of BMPs for logging, mine reclamation, and road-building operations. Private landowners are not required to use BMPs. By properly implementing and maintaining BMPs, onsite erosion and potential increases in sedimentation to creeks would be minimized, and soil erosion losses would be a minor cumulative impact.

3.19.4.6 Regulatory/Forest Plan Consistency

3.19.4.6.1 Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources; construct and maintain all roads so as to assure adequate drainage and to minimize or, where practicable, eliminate damage to soil, water, and other resource values; and reclaim, where practicable, the surface disturbed in operations by taking such measures as preventing or controlling onsite and off-site damage to the environment and forest surface resources.

Minimize Adverse Environmental Impact (36 CFR 228.8)

Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8 to minimize adverse environmental impacts. MMC did not propose to implement practicable measures to minimize erosion, maximize reclamation success, or minimize effect of road usage. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would incorporate additional feasible and practicable measures to minimize adverse environmental impacts. These measures include developing and implementing a final Road Management Plan and a Vegetation Removal and Disposition Plan; increasing the salvage and replacement of suitable soil materials for reclamation; removing a majority of coniferous forest debris removed before soil removal; and salvaging disturbed wetland soils for use in constructing new wetlands.

Roads (36 CFR 228.8(f))

In all mine and transmission line alternatives, roads would be constructed and maintained to ensure adequate drainage and to minimize or, where practicable, eliminate damage to soil, water, and other resource values. The Environmental Specifications describe how transmission line roads would be constructed and maintained to ensure adequate drainage and to minimize or eliminate damage to resource values. The agencies' transmission line alternatives would have less new road development in the watersheds of impaired streams, in watersheds of Class 1 streams, and on soils with severe erosion risk, high sediment delivery, and slope failure. The predicted delivery of sediment from roads to streams in the agencies' mine and transmission line alternatives would be less than in MMC's alternatives. At the end of operations, all mine and transmission line alternatives would have roads no longer needed for operations. The agencies' mitigation provides more specificity regarding management of roads no longer needed for operations. Such roads would be placed either in intermittent stored service or decommissioned. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8(f) as it relates to water quality because MMC did not propose to implement practicable measures to minimize adverse environmental impacts on soils. Mine Alternatives 3 and 4 Transmission Line Alternatives C-R, D-R, and E-R would comply with 36 CFR 228.8(f) as it relates to soils.

Compliance with 36 CFR 228.8(f) regarding roads management is discussed in section 3.6.4.11.4 *National Forest Management Act/Kootenai Forest Plan* (RF-2 through RF-5), beginning on page 453.

Reclamation (36 CFR 228.8(g))

All mine and transmission lines alternative would comply with the requirements of 36 CFR 228.8(g) regarding controlling erosion, controlling surface water runoff, and isolating toxic materials. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8(g) to implement practicable measures to prevent or control onsite and off-site damage to the environment and forest surface resources. MMC did not propose to implement practicable measures to minimize erosion and maximize reclamation success. The agencies' alternatives would include developing and implementing a final Road Management Plan and a Vegetation Removal and Disposition Plan; increasing the salvage and replacement of suitable soil materials for reclamation; removing a majority of coniferous forest debris removed before soil removal; consolidating soil stockpiles and reclaiming them incrementally; using primarily native species in revegetation and salvaging disturbed wetland soils for use in constructing new wetlands. These measures would minimize erosion and ensure reclamation success. The agencies' alternatives would comply with 36 CFR 228.(g) as it relates to soils.

3.19.4.6.2 Kootenai Forest Plan

Proposed lands allocated for the action alternatives would be reallocated to non-timber production land. Consequently, the only standards in the KFP that would apply to these lands would be the implementation of BMPs to control erosion and sedimentation. All mine and transmission line alternatives would comply with the KFP standard to use soil and water conservation practices and BMPs to minimize nonpoint source pollution. The agencies' alternatives would include more frequent BMP monitoring than MMC's alternatives.

3.19.4.6.3 State Requirements

Alternatives 3 and 4 would comply with the MMRA regarding disturbed lands being reclaimed to a post-mining land use with stability and utility comparable to that of the pre-mining landscape. Draft findings regarding compliance with MFSA requirements are discussed in the Summary, beginning on p. S-53.

3.19.4.7 Irreversible and Irretrievable Commitments

Some soil would be irreversibly lost under all action alternatives during soil removal, construction, and operation of the mine before the re-establishment of vegetation. Some soil would be irreversibly lost under transmission line Alternatives B through E-R, especially during construction and final reclamation of access roads. Soil productivity would be irreversibly lost in large areas under Alternative 2, along portions of access roads under Alternatives 3 and 4, and along transmission line access roads under all alternatives where single-lift salvage and replacement was used, because the soil profile would be altered and would require many years for soil productivity to return to pre-mine conditions. The time required to restore soil productivity would be shortened with the use of soil amendments. A minor amount of soil productivity would be irreversibly lost under all action alternatives along NFS road #278 due to widening of the road.

Irretrievable effects on soil productivity would result from prolonged soil stockpiling and at disturbances that would not be reclaimed until the end of mine life, such as at plant sites and most of Little Cherry Creek and Poorman Tailings Impoundment sites. Irretrievable effects on soil productivity would result along transmission line access roads where road prisms would remain until final reclamation of the transmission line. These irretrievable effects would be minimized with the use of fertilizers and mulches. Irretrievable effects on soil productivity would be limited at areas under Alternatives 3 and 4 where double-lift soil salvage and replacement was used. The replaced lift soils under Alternatives 3 and 4 also would have wood-based mulch and mycorrhizae incorporated into the upper 4 inches of soil. These measures would accelerate the rebuilding processes for respread soils to reach pre-mine productivity levels. Irretrievable effects on soil productivity would be limited on access roads of transmission line under Alternatives C-R through E-R with removal and replacement of the surface soil for final reclamation, and with the addition of wood-based mulch and mycorrhizae into the upper 4 inches of soil during final reclamation.

3.19.4.8 Short-term Uses and Long-term Productivity

Soil losses due to erosion would be long-term, but would return to natural rates Once vegetation is re-established and stabilized reclaimed areas, in about 3 to 5 years following reclamation. Over steepened and south- and west-facing cut slopes may require more than 5 years for the vegetation ground cover to reach predisturbance levels without soil amendments. Decreases in soil productivity would be long-term in all reclaimed areas. The degree of soil productivity losses would vary among the action alternatives and would be more severe under Alternative 2 and under transmission line Alternatives B through E-R in areas where single-lift soil salvage and replacement would be used. These areas primarily include the Ramsey Plant Site, the Little Cherry Creek Diversion Channel, mine roads, the Libby Adit Site, and all transmission line access roads. Due to mixing of soil horizons and prolonged storage, soil profile characteristics would be drastically changed over pre-mine conditions. Soil productivity would decrease under Alternative 2 on the top of the Little Cherry Creek Tailings Impoundment if 18 inches of soil were placed over crusted fine-grained tailings, which would restrict rooting depth.

3.19.4.9 Unavoidable Adverse Environmental Effects

Loss of soil development in the area would occur in all action alternatives. Soil erosion to some degree would occur under all action alternatives, even with implementation of proposed mitigation measures. The degree of effects of soil erosion would be more severe under Alternative 2 and less under Alternatives 3 and 4 because of the additional erosion control methods and the fewer acres of soil disturbance under Alternatives 3 and 4. Loss of soil productivity would be unavoidable under all action alternatives in all disturbances where soil was removed, stored, and replaced. The degree of effects on soil productivity would be more severe under Alternative 2 and under transmission line Alternatives B through E-R where single-lift soil salvage and replacement was used.

3.20 Sound, Electrical and Magnetic Fields, Radio and TV Effects

3.20.1 Regulatory Framework

3.20.1.1 Sound

Noise is generally defined as unwanted sound, and can be intermittent or continuous, stationary or transient. Noise levels heard by humans and animals depend on several variables, including distance and ground cover between the source and receiver and atmospheric conditions. Noise can influence humans or wildlife by interfering with normal activities or diminishing the quality of the environment. Noise levels are quantified using units of decibels (dB). The dBA scale begins at zero—the sound intensity at which sound becomes audible to a young person with normal hearing. Each 10 dBA increase in sound approximates a doubling in loudness, so that 60 dBA is twice as loud as 50 dBA. People generally have difficulty detecting sound level differences of 3 dBA or less.

No federal, KNF, or county regulations govern noise levels in the analysis area (Big Sky Acoustics 2006). The EPA identifies outdoor noise levels less than or equal to 55 dBA are sufficient to protect public health and welfare in residential areas and other places where quiet is a basis for use. The MDT determines that traffic noise impacts occur if predicted 1-hour traffic noise levels are 66 dBA or greater at a residential property during the peak traffic hour (Big Sky Acoustics 2006). Noise associated with the transmission line is required to be 50 dBA or less at the edge of the right-of-way in residential and subdivided areas unless the affected landowner waives this condition (ARM 17.20.1607.2 (a)).

3.20.1.2 Electrical and Magnetic Fields

"EMF" is an abbreviation for the electric field and magnetic field associated with electric power systems. In the United States, these systems and their associated transmission lines operate at a frequency of 60 hertz (Hz), and therefore create 60-Hz EMFs. EMFs occur in the environment naturally and as a result of human activity. Naturally occurring EMFs are created by the weather and the geomagnetic field. The electric power transmission and distribution system is the principal source of environmental 60-Hz EMFs. EMFs are weak except near power lines, substations, electrical machinery, and appliances.

Electric fields from power lines are created when a voltage is placed on the conductors, a step known as energizing the line. Electric fields exist in the space surrounding an energized object and have a strength measured by the unit "volt per meter" (V/m) or 1,000 volts per meter (kV/m). Electric field strength is determined by the voltage on the line and does not change with power flow. Electric field strength attenuates rapidly with increasing distance from the power line and can be reduced by trees with foliage and houses and greatly reduced by metal and other conducting surfaces.

Magnetic fields from power lines are created whenever current flows through power lines. The strength of the field is directly dependent on the current in amperes in the line but not the voltage. Magnetic field strength near electric power lines is typically measured in milligauss (mG). Similar to electric field strength, magnetic field strength attenuates rapidly with distance from the source, but unlike electric fields, magnetic fields are not easily shielded by ordinary objects and materials. Both electrical and magnetic fields are low energy, extremely low frequency fields, and should not be confused with high energy or ionizing radiation such as X-rays and gamma rays.

No federal, KNF or county regulations govern electrical and magnetic fields in the analysis area. Montana major facility siting regulations require that the electric field strength at the edge of the right-of-way be no greater than 1 kV/m in residential and subdivided areas unless the affected landowner waives this condition and that the electric field at road crossings be no greater than 7 kV/m (ARM 17.20.1607.2(d)). Montana has no regulation concerning 60-Hz magnetic fields of power lines.

3.20.1.3 Radio and TV Effects

Radio and television interference are collectively referred to as radio noise. Radio noise is a phenomenon produced by both corona and sparking and can vary greatly based on weather conditions. Television interference is significant only for foul weather conditions. Corona occurs when the electrical field at a particular point reaches a sufficiently high value to cause ionization of the surrounding air. Corona on transmission lines can cause power loss, radio, and television interference and audible noise near the transmission line.

No KNF, state or county regulations govern radio or television interference in the analysis area. The Federal Communications Commission (FCC) regulations pertaining to the prevention of radio and television interference vary by service. Such regulations are usually included in the operating requirements section for each service.

For transmission lines with normal conductor spacings and rights-of-way, a fair-weather radio interference level of about 40 decibel-microvolts per meter (dBμV/m) at a lateral distance of 100 feet from the outermost phase has been established as a guideline for identifying design criteria for a radio noise limit (Institute of Electrical and Electronics Engineers Standard 430-1991).

3.20.2 Analysis Area and Methods

The analysis area encompasses an area potentially affected by project facilities: along the Bear Creek Road south from US 2; the area surrounding the proposed mine facilities; and the area crossed by the four transmission line alternatives and associated access roads, and the Sedlak Park Substation site and loop line area.

3.20.2.1 Sound

Woodward-Clyde Consultants collected ambient noise levels measurements at the Ramsey Plant Site and the Little Cherry Creek Tailings Impoundment Site in 1988 (Woodward-Clyde Consultants 1989c). Ambient noise levels in the analysis area are unlikely to have changed significantly since 1988. Big Sky Acoustics completed two, 5-minute noise level measurements in 2005 above the Troy Mine mill and portal (Big Sky Acoustics 2006). The Troy Mine is located about 20 miles northeast of the proposed Montanore Project and uses similar underground mining and milling techniques. Big Sky Acoustics developed predicted noise level contours that would develop under various operating conditions using noise prediction software.

3.20.2.2 Electrical and Magnetic Fields and Radio and TV Effects

Power Engineers determined electrical and magnetic fields and radio and television interference for MMC’s proposed structure configuration (Power Engineers 2005a). A steel monopole structure 90 feet in height was used in the analysis. BPA's corona and field effects program was used in the calculations. A similar calculation using BPA's corona and field effects program was made for the H-frame structures that would be used in the other three transmission line alternatives (HDR Engineering 2007).

The lead agencies completed an evaluation of the potential for environmental impacts from transmission line EMFs (Asher Sheppard Consulting 2007, 2012). The evaluation addresses the current status of scientific knowledge concerning potential health effects from exposure to transmission line EMFs. For purpose of categorizing risk of exposure of a residence to EMFs, all residences within 0.5 mile, 200 feet, and 50 feet of the centerline were identified. Residences within 0.5 miles but greater than 200 feet (as the project would be constructed) are designated as Category I homes. Category I homes would have electric field strength always less than 50 V/m and the magnetic field strength always less than 1.0 mG, regardless of the pole type. Exposures in Category I homes are characterized as having "no recognized potential for a health impact from exposure to EMFs" (Asher Sheppard Consulting 2007, 2012). Montana regulations allow the final centerline to vary by up to 250 feet of the centerline (ARM 17.20.301 (21)) unless there is a compelling reason to increase or decrease this distance. Consequently, residences within 450 feet of the mapped centerline location were considered Category I. Similarly, identification of residences within the 0.5 mile corridor requires an increased distance of 2,890 feet from the mapped right-of-way centerline. Residences within 200 feet but greater than 50 feet from the centerline (as it would be constructed) are in Category II. At lateral distances from 50 feet from the centerline) to 200 feet away, the electric field strength would be no greater than 0.75 kV/m and the magnetic field strength no greater than 5 mG. This maximum electric field strength is below the level set by the Montana regulation for electric field strength and both the electric and magnetic field strengths are below the exposure levels for the general public recommended as reference levels or maximum permissible levels. Exposures at distances of 50 to 200 feet from the centerline (as it would be constructed) are characterized as having "questionable potential for a health impact from exposure to EMFs."

3.20.3 Affected Environment

3.20.3.1 Sound

Except for the Libby Adit Site, existing sound levels in the analysis area are low, characteristic of rural areas and wilderness (Table 168). Nighttime sound levels are 4 to 12 dB lower than daytime levels due to cessation of many human-related activities. Wind conditions during the monitoring period were low, less than 15 mph, eliminating wind as a significant sound source. Natural sound sources include wind, wildlife, water flow, thunder, and wind-induced noise such as the rustling of foliage. Other sound sources include vehicles, such as trucks or airplanes, and man. The overall contribution from human activities is small, and the predominant sound sources are natural. Wildernesses typically have very low noise levels. The Rock Creek Project Final EIS reported daytime noise levels at the CMW boundary of 25 to 27 dBA (USDA Forest Service and DEQ 2001).

Large-lot residential properties, ranches, and cabins are found along US 2 near Libby Creek Road (NFS road #231), Bear Creek Road (NFS road #278), the Fisher River, Pleasant Valley, and Schrieber Lake. Twenty residences or cabins are within 1 mile of the four transmission line alternatives. Most of these properties are within 0.5 mile of US 2.

Table 168. Summary of Ambient Sound Measurements.

Measurement Period	Little Cherry Creek Impoundment Site	Ramsey Plant Site
Midweek		
Day (Ld)	39.0	41.3
Night (Ln)	35.5	28.8
Average 24-hour (Ldn)	42.6	40.5
Weekend		
Day(Ld)	28.6	40.1
Night (Ln)	22.7	31.3
Average 24-hour (Ldn)	30.6	40.6

Source: Woodward-Clyde Consultants, Inc. 1989a.

3.20.4 Environmental Consequences

3.20.4.1 Sound

3.20.4.1.1 Alternative 1 – No Mine

The analysis area would continue to have quiet sound levels characteristic of rural areas and wilderness lands. Existing noise levels would not change. Activities on private land at the Libby Adit Site would remain until reclaimed in accordance with existing permits and approvals. These activities would increase ambient noise levels near the adit.

3.20.4.1.2 Alternative 2 – MMC's Proposed Mine

Construction Phase

During the Construction Phase, noise would be produced by heavy equipment, such as scrapers, bulldozers, graders, loaders, and rock trucks. The noise produced by diesel-powered equipment typically is 85 dBA at a distance of 50 feet from the equipment. Equipment noise can vary considerably depending on age, condition, manufacturer, use during a time period, and a changing distance from the equipment to a listener location. To minimize equipment noise, MMC would supplement backup beepers on surface equipment with strobe light-type warning devices and the sound level of the backup beepers would be reduced to the minimum level necessary to comply with safety regulations.

Generators would be used to supply power as the adits were developed, and each generator is predicted to produce a noise level of about 82 dBA at 50 feet. Ventilation fans would be located outside of the adit portals, and include inlet and discharge attenuators to meet a total noise level of 85 dBA at 3 feet (Big Sky Acoustics 2006). Noise from the generators and fans would extend into the CMW, reaching about 30 dBA along the ridge between Elephant Peak and Bald Eagle Peak (Big Sky Acoustics 2006). These sound levels in the CMW would be slightly above existing levels, affecting recreational users of this portion of the CMW. Noise from generators would cease after 2 to 3 years when the transmission line was completed.

Highest noise levels would be generated periodically at the Ramsey Plant Site as a result of blasting. Blasting noise near the surface during the preproduction phase is predicted to be equal to 122 dBA at 0.6 mile from the Ramsey Plant Site, and equal to the existing ambient noise level at up to about 8 miles from the site. Blasting noise would be greatest during initial adit construction; as the adits go deeper, blasting noise would decrease. The Rock Lake Ventilation Adit would be constructed from the mine to the surface. Very short-term blasting would be necessary when the adit daylighted on private land east of and above Rock Lake.

Construction Phase activities also would include: hauling of waste rock to the Little Cherry Creek Impoundment Site; excavation of borrow material from the Little Cherry Creek Impoundment Site; and construction of a Starter Dam, Diversion Channel and Seepage Collection Dam at the Little Cherry Creek Impoundment Site. Noise levels between 30 and 40 dBA would be experienced in areas within 2.5 miles of the source, depending on the topography and atmospheric conditions. Some blasting may be necessary in the upper part of the diversion channel. Elevated noise levels from blasting would be short and intermittent.

Construction truck traffic over a 1-year period to and from the Plant Site, Tailings Impoundment Site, and Libby Loadout would increase noise levels on the Libby Creek Road (NFS road #231) while the Bear Creek Road was reconstructed. Trucks with properly operating mufflers is expected to generate up to an estimated 86 dBA at 50 feet. Trucks using Jake brakes with straight pipe mufflers would produce sound levels of 98 dB(A) at 50 feet, and would be audible at distances of up to 1 mile. Similar noise levels would occur along the Bear Creek Road (NFS road #278) during the construction period. The noise effects would be similar to those of trucks transporting logs from a timber sale. These haul trucks would affect residences adjacent to the access road.

Operations Phase

Noise at the Ramsey Plant Site would be slightly less during operations than during the Construction Phase. Ore would be processed inside the mill buildings. Noise from enclosed milling operations is typically audible as a low level hum, and was measured as 49 dBA at about 328 feet near the Troy Mine plant (Big Sky Acoustics 2006). Noise levels greater than the EPA guideline of 55 dBA would occur in the immediate vicinity of the Ramsey Plant Site, but would decrease substantially with distance from the mill. For example, noise levels at the Troy Mine were 49 dBA 330 feet from the mill. Noise levels between 30 and 55 dBA would extend into the CMW to Elephant Peak and down the Ramsey Creek drainage to about the LAD Area 1 (Big Sky Acoustics 2006). At all project facilities, backup beepers on surface equipment would be supplemented with strobe light-type warning devices. The sound level of the backup beepers would be reduced to the minimum level necessary to comply with safety regulations. These sound levels in the CMW would be slightly above existing levels, affecting recreational users of this portion of the CMW.

The air-intake fan associated with the Rock Lake Ventilation Adit would be located inside the mine, and not at the portal. The walls of the raise and adit would reduce the noise from the fan at the surface. Noise level at the portal of the Rock Lake Ventilation Adit is estimated to be 16 dBA and would not be audible over ambient noise levels (Big Sky Acoustics 2006).

Noise at the Little Cherry Creek Impoundment Site and LAD Areas would be generated by heavy equipment during construction and by occasional vehicular traffic, pumps and associated equipment, and bulldozers during operations. The sound from bulldozers would be periodic. In general, the production phase noise levels are predicted to be equal to 55 dBA within about 0.2 mile of the facility, and would be equal to the lowest measured existing ambient noise level of 30 dBA within about 2.5 miles of the sites (Big Sky Acoustics 2006).

Truck and train traffic and heavy equipment would increase noise at the Libby Loadout. Loadout activities would generate sound levels similar to other operations. The increased noise levels would be less noticeable because of higher ambient noise levels.

Closure Phase

After operations cease, MMC would remove all facilities from the plant and adit sites. Reclamation at the Ramsey Plant Site, the Libby Adit Site, and the Rock Lake Ventilation Adit Site would take several years. Noise at these locations would be generated by heavy equipment during reclamation and by occasional vehicular traffic. Heavy equipment also would be used at the tailings impoundment. The decommissioning and closure period is expected to require a minimum of 10 years, and possibly up to 25 years of monitoring (Klohn Crippen Consultants 2005). Reclamation activities would generate sound levels similar to the Operations Phase. At the end of reclamation, noise levels at all project facilities would return to pre-mine levels. Traffic and activities associated with any long-term monitoring or water treatment would generate slightly increased noise levels.

3.20.4.1.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Noise sources and general magnitude of effects during all phases of operations in Alternative 3 would be similar to Alternative 2. Ventilation adits would be in Libby Creek and near Rock Lake. During construction of the adits, elevated noise levels would extend up and down the Libby Creek drainage in a similar manner as in Ramsey Creek in Alternative 2. Noise from the generators and fans would extend into the CMW, reaching about 30 dBA along the ridge between Elephant Peak and Ojibway Peak. Noise from generators would cease after 2 to 3 years when the transmission line was completed.

Construction of the Libby Plant Site would increase noise levels in the lower Ramsey Creek drainage and in the Libby Creek drainage east of the Libby Adit. Recreational users at the Libby Gold Panning Recreation Area would experience noise levels between 45 and 55 dBA.

3.20.4.1.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Noise sources and general magnitude of effects during all phases of operations at the Libby Plant Site, Upper Libby Adit Site and LAD Areas 1 and 2 in Alternative 4 would be the same as in Alternative 3. Noise effects at the Little Cherry Creek Impoundment Site would be the same as Alternative 2.

3.20.4.1.5 Alternative A – No Transmission Line

In Alternative A, the transmission line, substation, and loop line for the Montanore Project would not be built. Noise levels associated with the existing 230-kV BPA transmission line would not change. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

3.20.4.1.6 Alternative B – MMC's Proposed Transmission Line

Noise During Transmission Line Construction, Operations, and Decommissioning

Transmission line construction would temporarily increase daytime ambient noise levels along the transmission line corridor. During the estimated 6-month transmission line construction period, construction equipment such as bulldozers, loaders, and haul trucks would generate 100 to 120 dB(A) at 50 feet. Chain saws and logging trucks used in forest clearing for the line would generate similar noise levels. These sounds would generally occur in hilly, forested areas, which would serve to reduce sound audibility. A helicopter may be used for four activities, depending on the construction contractor, structure placement, line stringing, timber harvest, and annual inspection and maintenance. Helicopters may be used for logging steep terrain. Logging may take one to two months, depending on the area logged. Structure placement and line stringing would take a week or two each. Annual inspections may take about a week. Increased noise levels would be audible to residences along US 2 (Figure 79) and recreational users at the Libby Creek Recreation Gold Panning Area and on trails along the alignment of this alternative. Similar helicopter noise would be audible during annual inspections of the line. When the line and structures were removed at mine closure, noise from helicopters, vehicles and other heavy equipment would be audible residences along US 2 and recreational users at the Libby Creek Recreation Gold Panning Area and on trails along the alignment. Some residents may perceive air pressure changes as vibrations from the helicopter use.

Because of generally low ambient background noise levels, the transmission line clearing, road construction, and line construction activities would be generally audible for about 2.5 miles, depending on the topography and atmospheric conditions. This could include the campground at Howard Lake and homes and recreational use areas along the Fisher River valley. Equipment trucks or logging trucks could extend the audible area. All off-site truck traffic would temporarily increase noise levels at residences adjacent to travel routes to and from the construction area. The effects would be similar to logging trucks transporting logs from an active timber sale area. The increased noise levels would be short-term, and would return to ambient levels when the noise-generating activity was completed.

Transmission Line Noise

The proposed 230-kV electrical power transmission line would produce soft hissing and crackling sounds in wet weather. In fair weather, these noises are virtually inaudible. During the light rains or wet snows which occur about 10 percent of the time in the analysis area, the transmission line would produce a noise level of about 50 dB(A) at the edge of the right-of-way (Power Engineers 2005a). The closest residence to MMC's proposed centerline would be about 380 feet away; two other residences along US 2 are within 450 feet from the centerline. The proposed centerline may vary up to 250 feet from the final centerline in final design. Expected noise levels at a residence about 380 feet from the centerline during a light rain or wet snows would be between 40 and 45 dBA (Power Engineers 2005a). This sound level would be slightly above naturally occurring levels and would be faintly discernible. The sound level would be less than 20 dBA during fair weather, and would not be audible over existing sounds.

Noise During Substation Construction, Operations, and Decommissioning

Noise generated during construction of the Sedlak Park Substation would be similar to construction of the mine facilities. Typical construction equipment generates noise between 60 to 70 dBA at 400 feet from the site, which is about the distance to the nearest residence. Construction would take 12 to 18 months. Because BPA's Sedlak Park Substation would not contain a transformer, there would be no audible hum emanating from the substation. Whenever breakers were to open and close, an audible noise would be heard by those in close proximity to the substation. The noise would be infrequent, occurring no more than a few times per year, and would be no louder than the noise from a shotgun blast.

3.20.4.1.7 Transmission Line Alternatives C-R, D-R, and E-R

Noise During Transmission Line Construction, Operations, and Decommissioning

Noise sources and general magnitude of effects during all phases of construction operations, and decommissioning in Alternatives C-R, D-R and E-R would be similar to Alternative B. Noise associated with BPA's Sedlak Park Substation also would be the same as Alternative B.

Selected structures would be constructed and timber harvested with helicopter. Depending on the alternative, noise levels in the upper part of the Miller Creek tributary (Alternative C-R), Miller Creek (Alternative D-R) and along West Fisher Creek and Standard Creek (Alternative E-R) would experience noise from helicopters, heavy equipment, and chain saws between the work location and staging area during construction. Similar noise levels would be audible during annual inspections, and final line decommissioning. Helicopters would be used for five activities: logging, structure placement, line stringing, and annual inspection and maintenance, and decommissioning. Logging may take one to two months and structure placement and line stringing would take a week or two each. Annual inspections may take about a week. Increased noise levels would be audible at private residences along US 2 where the alignment crosses the Fisher River, at private residences near Howard Lake in Alternatives D-R and E-R, and at a private residence along West Fisher Creek in Alternative E-R. In Alternatives C-R, D-R and E-R, recreational users at the Libby Creek Recreation Gold Panning Area and on trails along the alignment would experience higher noise levels during construction, annual inspections, and decommissioning. The increased noise levels would be short-term, and would return to ambient levels when the noise-generating activity is completed.

The alignment in the Miller Creek and West Fisher Creek Alternatives would follow NFS road #231 east of Howard Lake. At the closest location, the alignment in these two alternatives would be about 1,300 feet east of the Howard Lake Campground and about 1,000 feet east of the eastern shore of Howard Lake. Recreational users at the campground and Howard Lake would experience higher noise levels during construction, annual inspections, and decommissioning. The increased noise levels would be short-term, and would return to ambient levels when the noise-generating activity is completed.

Transmission Line Noise

All residences are more than 450 feet of the centerline of the agencies' alternatives. As part of these alternatives, the centerline would be no closer than 200 feet from any residence during final design. Expected noise levels at a residence 200 feet from the centerline during a light rain would be about 42 dBA and less than 40 dBA at 300 feet (HDR Engineering, Inc. 2007) and probably would not be noticeable over existing noise levels.

3.20.4.1.8 Effectiveness of Agencies' Mitigation Measures

The Libby Plant Site in the agencies' mine alternatives would be about 2 miles farther from the CMW than the Ramsey Plant Site proposed by MMC. The Libby Plant Site would effectively minimize noise in the CMW. The agencies' mitigation of placing the centerline no closer than 200 feet from any residence would be effective in minimizing transmission line noise effects.

3.20.4.2 Electrical and Magnetic Fields

3.20.4.2.1 Alternative A – No Transmission Line

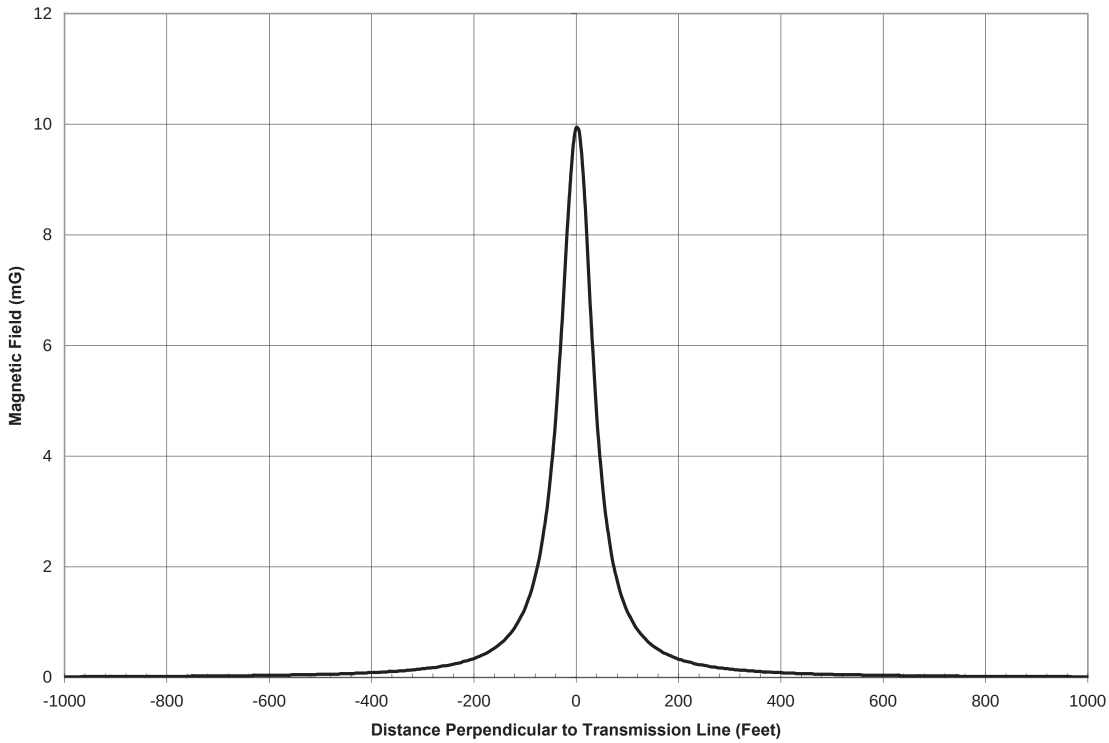
In Alternative A, the transmission line, substation, and loop line for the Montanore Project would not be built. Existing electrical and magnetic fields associated with the existing 230-kV BPA transmission line would not change. If existing residences are typical of others in the United States, average residential electric fields would be less than 10 V/m and magnetic fields of the order of 1 mG or less. EMFs of these levels are not known to have the potential for an adverse effect on health. In this alternative, the residences would have no recognized potential of an EMF health impact.

3.20.4.2.2 Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

Within 0.5 mile of this alignment, 14 residences are present, of which 11 are greater than 450 feet from the centerline of the right-of-way and the remaining three are within 450 feet. Because the final alignment could vary by up to 250 feet of the centerline analyzed in this EIS (ARM 17.20.301 (21)), three residences may be within 200 feet of the centerline depending on final transmission line alignment. At lateral distances from the edge of the right-of-way (50 feet from the centerline) to 200 feet away, the electric field strength would range from about 0.75 kV/m at 50 feet to about 0.05 kV/m (or 50 V/m) at 200 feet. The magnetic field strength would be about 4 mG at 50 feet and less than 1 mG at 200 feet (Chart 20). This maximum electric field strength at 50 feet would be below the level set by Montana regulation for subdivided and residential areas for electric field strength and both the electric and magnetic field strengths at 50 feet would be below the exposure levels for the general public recommended as reference levels or maximum permissible levels (Asher Sheppard Consulting 2007, 2012).

The Sedlak Park Substation would the closest electrical facility to a residence in all alternatives. The substation would be about 350 feet south of BPA's existing 230-kV centerline. The edge of the substation would be 600 feet from the residence, and the electric field strength would be less than about 0.05 kV/m (or 50 V/m) and the magnetic field strength would be less than 1.0 mG. Based on the electric and magnetic field strengths recommended in guidelines as reference levels or maximum permissible levels for the general public, and the current state of scientific research on EMFs, the substation would be categorized as having no recognized potential for a health impact from exposure to EMFs.

Chart 20. Calculated Magnetic Field Strength for MMC's Proposed Monopole Structures.



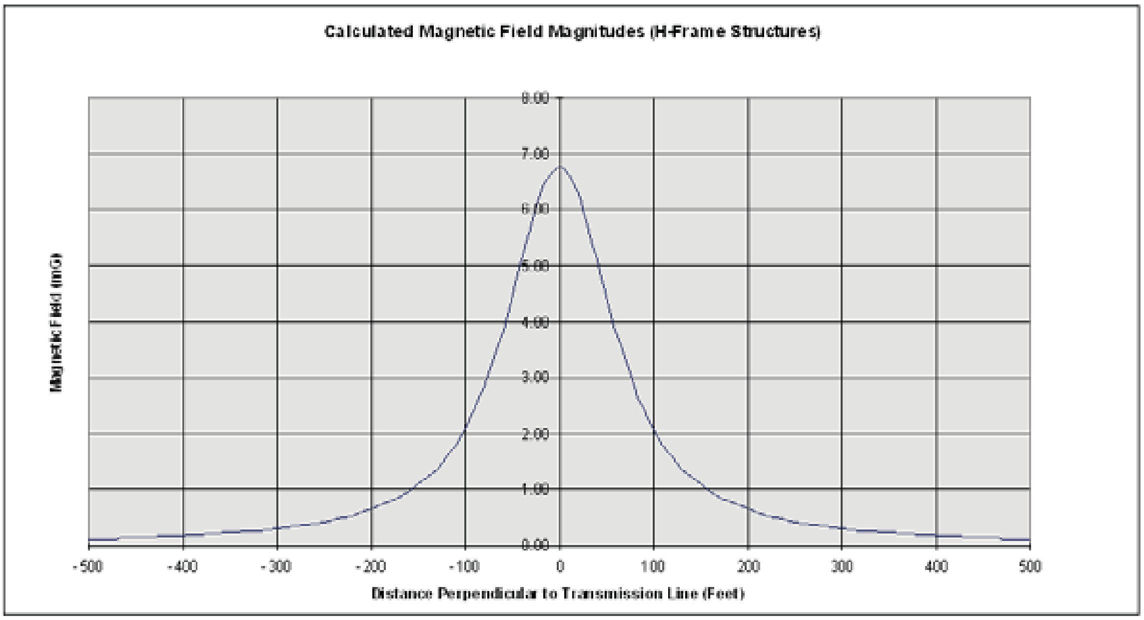
Source: POWER Engineers (2005), Fig. 5.

3.20.4.2.3 Transmission Line Alternatives C-R, D-R, and E-R

All four residences along the Modified North Miller Creek Alternative and all six residences along the Miller Creek Alternative and West Fisher Creek Alternative within 0.5 mile are greater than 450 feet from the proposed centerline. The electric field strength would be less than about 0.05 kV/m (or 50 V/m) and the magnetic field strength would be less than 1.0 mG (Chart 21). Based on the electric and magnetic field strengths recommended in guidelines as reference levels or maximum permissible levels for the general public, and the current state of scientific research on EMFs, these alternatives are categorized as having no recognized potential for a health impact from exposure to EMFs (Asher Sheppard Consulting 2007, 2012).

All residences are more than 450 feet of the proposed centerline of the agencies' alternatives. As part of these alternatives, the centerline would be no closer than 200 feet from any residence during final design. For residences 200 feet or more from the centerline, the electric field strength would be about 0.05 kV/m (or 50 V/m) and the magnetic field strength would be less than 1 mG. Based on the electric and magnetic field strengths recommended in guidelines as reference levels or maximum permissible levels for the general public, and the current state of scientific research on EMFs, all agencies' alternatives are categorized as having no recognized potential for a health impact from exposure to EMFs (Asher Sheppard Consulting 2007, 2012).

Chart 21. Calculated Magnetic Field Strength for Agencies' Proposed H-Frame Structures.



Source: HDR Engineering, Inc. 2007.

3.20.4.2.4 Effectiveness of Agencies' Mitigation Measures

The agencies' mitigation of routing the alignments in the agencies' alternatives more than 200 feet from the proposed centerline would be effective in minimizing exposure to magnetic fields. All residences are more than 450 feet of the centerline of the agencies' alternatives. As part of these alternatives, the centerline would be no closer than 200 feet from any residence during final design. All agencies' alternatives are categorized as having no recognized potential for a health impact from exposure to EMFs.

3.20.4.3 Radio and TV Effects

3.20.4.3.1 Alternative A – No Transmission Line

In Alternative A, the transmission line, substation, and loop line for the Montanore Project would not be built. Radio and TV interference associated with the existing 230-kV BPA transmission line would not change.

3.20.4.3.2 Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

The transmission line would generate radio noise that may interfere with AM radio and television reception close to the line. FM broadcasts and 2-way communications generally would not be affected. The effect of the line on AM radio and TV interference would decrease rapidly as distance from the line increases. The closest residence to the North Miller Creek Alternative is 380 feet from the proposed centerline, west of US 2 (Asher Sheppard Consulting 2007, 2012). Under Montana's regulations, the proposed centerline may vary up to 250 feet from the final centerline in final design. The calculated radio interference at the closest residence of MMC's proposed centerline (380 feet) would be between 40 and 45 dBμV/m for the rain-weather condition and around 25 dBμV/m for the fair-weather condition. The calculated television interference at the closest residence (380 feet) would be about 8 dBμV/m for the rain-weather condition. A guideline for radio noise is a fair-weather level of about 40 dBμV/m at a lateral distance of 100 feet from the outermost phase (Power Engineers, Inc. 2006a).

If interference were to occur once the line was energized, MMC or the operating utility would correct the interference as required by FCC regulations and MMC's Environmental Specifications (MMI 2005b). Correction of interference would depend on site-specific circumstances. According to FCC regulations, the line must not degrade radio or TV reception beyond current levels. Typically, changes in line operation or measures such as installation of remote antennae correct most interference problems (Power Engineers, Inc. 2006a). Possible radio and TV interference problems along the transmission line typically cannot be accurately identified until the final line location and design are known.

3.20.4.3.3 Transmission Line Alternatives C-R, D-R, and E-R

The three other transmission line alternatives would use the eastern alignment and route the line east of the most of the residences along US 2. All residences are greater than 450 feet of the centerline of the agencies' alternatives and would not be affected by radio interference. The agencies' Environmental Specifications (Appendix D) would govern radio and television interference.

3.20.4.4 Cumulative Effects

Past actions and current actions, such as the activity at the Libby Adit Site, and vehicular traffic and NFS roads, have increased ambient noise levels over that of an undisturbed forest. The existing BPA transmission line also has EMF near the line. The KNF's Miller-West Fisher Vegetation Management Project will consist of vegetative treatments including timber harvest, slash treatment, site preparation, prescribed burning, tree planting, precommercial thinning, construction of new roads, road storage and decommissioning activities, road reconstruction, and implementation of BMPs. Depending on the timing of these activities and construction of the transmission line, noise from equipment and helicopters may be cumulatively greater in the Miller Creek and West Fisher Creek drainages. Many of the reasonably foreseeable actions would use the same roads as the Montanore Project. The reasonably foreseeable actions and the Montanore Project would cumulatively increase traffic noise near access roads. Cumulative noise levels would be unlikely to exceed 55 dBA. The Rock Creek and Montanore projects would not have cumulative effects.

3.20.4.5 Regulatory/Forest Plan Consistency

The applicable Montana administrative rules require that the electric field strength at the edge of the right-of-way be no greater than 1 kV/m in residential and subdivided areas and at road crossings be no greater than 7 kV/m. Calculations performed under assumptions of line operating conditions that would produce maximum strength electric and magnetic fields do not exceed these restrictions (Power Engineers 2005a, HDR Engineering, Inc. 2007). Montana has no rule or regulation concerning 60-Hz magnetic fields of power lines. Montana also requires that transmission lines be constructed in conformity with the National Electric Safety Code. All proposed transmission line alternatives would meet this requirement. In addition, MMC would be required to prevent unacceptable interference with stationary radio, television, and other communication systems as a condition of the certificate. In summary, all transmission line alternatives would comply with Montana rules concerning EMF levels and transmission line safety.

3.20.4.6 Irreversible and Irretrievable Commitments

The quiet sound levels characteristic of the analysis area would be irretrievably lost during the Construction, Operations, and Closure Phases.

3.20.4.7 Short-term Uses and Long-term Productivity

Elevated noise and EMF levels in all action alternatives would cease at mine closure and transmission line decommissioning, and would be a short-term use of the existing environment.

3.20.4.8 Unavoidable Adverse Environmental Effects

Elevated noise levels in upper Libby Creek would occur during the reclamation of the Libby Adit in the No Action Alternative. Similar noise levels would occur during construction, operations, and reclamation would occur between Libby Creek and the Cabinet Mountains in all mine action alternatives. Elevated noise from equipment and helicopter use in drainages in which the transmission line would be built would occur in all transmission line action alternatives.

3.21 Transportation

The transportation resource consists of a network of roadways that would be used during activities related to the proposed mine and transmission line. This section discusses the effects on roadway level of service and safety. Effects on public access in the analysis area are discussed in section 3.16, *Recreation*.

3.21.1 Regulatory Framework

The roads analysis complies with regulations governing the administration of the Forest Transportation System (36 CFR 212) and with the Forest Service Transportation Administrative Policy FSM Chapter 7700 (2001). The Forest Service regulations intended to help ensure that additions to the National Forest System road network are those deemed essential for resource management and use; that construction, reconstruction, and maintenance of roads minimize adverse environmental impacts; and that unneeded roads are decommissioned and restoration of ecological processes are initiated. Current Forest Service roads policy requires a science-based transportation analysis (USDA Forest Service 1999b). The Forest Service's locatable minerals regulations (36 CFR 228.8) require mine operators to construct and maintain all roads so as to assure adequate drainage and to minimize or, where practicable, eliminate damage to soil, water, and other resource values.

KFP goals, objectives, and standards that apply to Forest System Roads (roads wholly or partly within or adjacent to and serving the National Forest System and which are necessary for the protection, administration and utilization of the National Forest System and the use and development of its resources) are discussed below. Applicable general Forest-wide goals and objectives address road densities, soil erosion, and water quality concerns. Applicable KFP standards governing roads are that development activities will be rigorously examined to ensure that the minimum number and length of roads are constructed to the minimum standard necessary. The KFP, which incorporates INFS standards, establishes stream, wetland, and landslide-prone area protection zones called RHCAs, and set standards and guidelines for managing activities that potentially affect conditions within the RHCAs. INFS standards applicable to roads are discussed in section 3.6*, Aquatic Life and Fisheries.*

US 2 is a federal highway owned and maintained by the MDT. Any modification of the existing Bear Creek Road/US 2 intersection or Libby Creek Road/US 2 intersection, and construction of an approach road to the Sedlak Park Substation would be in MDT's right of way. Approval for these activities in MDT's right of way would be under its jurisdiction.

3.21.2 Analysis Area and Methods

3.21.2.1 Analysis Area

In Alternative 2, MMC would use US 2, NFS road #278 (Bear Creek Road), 1.7 miles of new access road, and NFS road #4781 (Ramsey Creek Road) to access the plant site and tailings impoundment. About 10 miles of the Bear Creek Road (NFS road #278), from US 2 to the Bear Creek bridge, would be chip-sealed. The road width would be upgraded to 20 to 29 feet wide. US 2 would be used from Libby, Montana (US 2 milepost (MP) 32.7) to the intersection with Bear Creek Road (MP 39.7). NFS road #6210 (between Ramsey Creek and Libby Creek) would be used as an access road to the Libby Adit. While the Bear Creek Road is upgraded in the first 2 years, NFS road #231 (Libby Creek Road) would be used for access.

In Alternatives 3 and 4, MMC would use the same segment of US 2 between Libby and the intersection with Bear Creek Road, and the Bear Creek Road to the tailings impoundment site. The Bear Creek Road would be paved with hot mix asphalt, and the asphalt road surface would then be chip-sealed. The roadway width would be upgraded to two 12-foot wide travel lanes and two shoulders of 1 foot, for a total width of 26 feet. Additional widening would be necessary on curves and short segments of new road would be needed.

During transmission line construction, MMC would use US 2 from Libby to Sedlak Park (MP 58.8). Depending on the transmission line alternative selected, MMC would use other NFS roads, such as the Miller Creek Road (NFS road #385), or the Libby Creek Road (NFS road #231). Proposed road use and new road construction in each transmission line alternative is discussed in Chapter 2. None of the new roads would be open to public access; these roads would only be used by MMC for access to the transmission line.

No airports, air strips, helipads, or metal pipelines are in the analysis area; these areas are not discussed further. Ken Justice, a pilot with the ALERT Air Ambulance Service at the Kalispell Regional Medical Center indicated US 2 is not used as a corridor for helicopters and that the preferred route is the Kootenai River corridor (Justice, pers. comm. 2008). No railroads are near the mine area or transmission line corridors. Concentrate would be shipped via rail from the Libby Loadout. MMC’s concentrate shipments would be relatively small, and effects on rail traffic are not discussed further.

3.21.2.2 Methods

To establish the base traffic conditions, the amount of traffic on the roadway system during the time period of the proposed mine operations without mine-related traffic was estimated. The proposed mine traffic was then added to the base levels, and the extent to which the mine traffic affects the service level of the roadway network was then determined. Safety was analyzed by calculating the additional number of accidents that may result from the increases in mine-related traffic. Intersections within the roadway network were examined to determine if the roadways need to be modified to accommodate increased levels of traffic. Because transmission line access roads would be used most heavily during construction and line decommissioning, and traffic volumes would be relatively small and short-term, an assessment of traffic congestion and safety was not completed on them.

3.21.2.2.1 Time Period

The analysis area includes the roadways to be used by mine traffic during start up, operating, and Closure Phases. For purposes of analysis, the lead agencies assumed construction would start in 2010. Mine start up construction activities would last 3 years until 2013. The mine would operate until 2029, for 16 years. Three additional years of operation may occur.

After operations are completed, the mine would be closed. For purposes of this transportation analysis, the reclamation and monitoring activities are assumed to last 10 years, until 2039. Upon completion of mining operations, traffic volumes would be greatest during the first two years for reclamation activities. Traffic would be minimal during post-closure monitoring activities. The analyses were projected for 19 years, starting in 2010. Although actual timelines for the mine may change from the timeline proposed (for example, if construction would start in 2014 instead of

2010), the magnitude and duration of the effects of mine-related traffic on the transportation system would remain relatively the same.

3.21.2.2.2 Traffic Volumes

MMC provided estimates of mine-related daily traffic volumes and vehicle types anticipated to use the roadway system during operation of the proposed mine (MMI 2005a, MMC 2008). The MDT and the KNF provided traffic data for US 2 and National Forest System roads. Future traffic volumes were estimated using traffic volumes in 2002 as the base year and the growth rate experienced on US 2 (1.2 percent). MMC's volumes and types were added to the traffic data supplied by the MDT and the KNF. In addition to traffic data, the MDT supplied design plans for the segments of US 2 from Libby to the Libby Creek Road turnoff; these design plans were used to complete the intersection safety analysis at US 2 and Bear Creek Road.

3.21.2.2.3 Traffic Congestion

The quality of service that a roadway provides is a measure of the amount of traffic congestion on a roadway for a particular volume of traffic. The quality of service is measured using the concept of levels of service (LOS). Six LOSs are as defined by the Transportation Research Board (TRB) in the Highway Capacity Manual. The six LOSs are A, B, C, D, E, and F, with LOS of A being the least congested, or best condition, and LOS of F being the most congested, or worst condition. Any roadway section determined to be functioning at LOS A, B or C is considered to be operating acceptably (Highway Capacity Manual 2000).

An LOS analysis was completed for US 2 and for the intersection of US 2 and Bear Creek Road. These analyses were completed for peak hour traffic during the day and represent the maximum amount of traffic congestion expected. For most of the time, the roadways would not experience the peak hour traffic used in the analysis.

For two-lane highways, such as US 2, each LOS is defined by percent time spent following another vehicle and average travel speed, as shown in Table 169. US 2 is a class 1 highway, which is a highway where efficient mobility is paramount. For intersections without traffic lights, such as the two-way, stop-controlled (TWSC) intersection at US 2 and Bear Creek Road, each LOS is defined by a range of delay times, measured in seconds that an individual vehicle will experience completing an individual turning movement during the peak hour volume (Highway Capacity Manual 2000). The LOS criteria for TWSC intersections are also shown in Table 169. The intersection of US 2 and the Libby Loadout access road was not analyzed due to the low level of anticipated use by MMC-related vehicles, which would be about one truck per hour during day shift operating hours.

The intersections of US 2 and Libby Creek Road and US 2 and the proposed Sedlak Park Substation access did not warrant analysis because the limited amount of traffic that would use them during construction activities would not affect the operation of the intersection. Congestion on Bear Creek Road and Libby Creek Road also was not analyzed because the Highway Capacity Manual analysis methods do not apply to recreational roads. A recreational road is not used for mobility, or to get from point A to point B in the fastest time, which is the basis of the two-lane highway analysis in the Highway Capacity Manual.

3.21.2.2.4 Safety

The safety of a particular section of highway is measured by the number of crashes per million vehicle miles traveled, called the accident rate. Typically, if there are no changes to a portion of

Table 169. Level of Service Criteria Used in Congestion Analysis.

Level of Service	Criteria for Two-Lane Highways in Class 1		Criteria for TWSC Intersections
	Percent Time Spent Following	Average Travel Speed (mph)	Average Control Delay (sec/vehicle)
A	< 35	> 55	0 to 10
B	> 35 to 50	> 50-55	>10 to 15
C	> 50 to 65	> 45 to 50	>15 to 25
D	> 65 to 80	> 40 to 45	>25 to 35
E	> 80	> 40	> 35 to 50
F	Applies whenever the flow rate exceeds the segment capacity		> 50

TWSC = two-way, stop-controlled.
Source: Highway Capacity Manual 2000.

highway that could affect the number of crashes and the roadway congestion is not severe, then as the amount of traffic increases, the number of accidents also increases proportionally by the accident rate. Because the proposed mine project would result in increased traffic on the area roadways, the number of accidents also may increase. The additional number of accidents that may result from the mine-related traffic was calculated for existing and future traffic conditions.

The intersection of US 2 and Bear Creek Road also was analyzed to determine if the intersection met current sight distance requirements and if turning lanes were required based on additional mine-related traffic. The sight distance and turning lane requirements for the intersection were analyzed using current MDT design criteria from the Montana Road Design Manual (MDT 2000).

3.21.3 Affected Environment

3.21.3.1 US 2

US 2 is a Non-Interstate National Highway and the northernmost U.S. highway. It provides access for eastbound and westbound travel across the continental United States. In Montana, the MDT classifies US 2 as a principle arterial.

Average annual daily traffic volumes along US 2 near the intersection of US 2 and NFS road #278 (Bear Creek Road) from 2002 through 2011 ranged from 1,740 vehicles per day in 2002 to 1,940 vehicles per day in 2010. The data were used to develop traffic growth rates for this section of roadway in the analysis (MDT 2012).

Within the analysis area, from the city of Libby (MP 32.7) to the intersection with MT 482 in the city of White Haven (MP 36.1), US 2 is a two-way, four-lane, undivided highway with a total width of 68 feet. The road consists of 12-feet travel lanes, 10-feet shoulders, and is bounded on both edges by curb and gutter. South of the intersection with MT 482, US 2 reduces in width to a two-way, three-lane, undivided highway. The eastbound direction remains at two lanes to MP 36.6. The westbound direction is a single travel lane. The roadway edges change from a curb and gutter to a shoulder and ditch section. At MP 36.6, US 2 reduces to a two-way, two-lane highway that is a total width of 46 feet and consists of 12-feet travel lanes and 11-feet shoulders. The shoulder width remains 11 feet until MP 37.4, where it reduces to 1.5 feet. The narrow shoulder condition continues to Libby Creek Road.

Proceeding east from the city limit boundary for the town of Libby, the posted regulatory speed limit is 40 mph to MP 33.4 (0.6 mile), increases to 50 mph to the end of the three-lane roadway section at MP 36.4 (east of White Haven), and increases to 70 mph for passenger vehicles, and 65 mph for trucks on the remainder of the two-lane roadway within the analysis area. The roadway surface is asphalt. Based on roadway plans provided by MDT, the roadway geometry is curvilinear and the terrain is level between Libby and White Haven and rolling east of White Haven. Initially constructed in the 1930s, the road was resurfaced and rehabilitated in 1998 and 1999.

Accident information including accident rates for US 2 from MP 39.0 to MP 40.5 was supplied by MDT. Accident information is presented in Table 170. The accident rate for US 2 between MP 39.0 to MP 40.5 is 2.33 accidents per million vehicle miles traveled for the 7-year period 2001 to 2007, higher than the statewide average. The accident rate for all rural non-interstate national highways in Montana from 2006 to 2010 was 1.04 accidents per million vehicle miles traveled. From 2007 to 2011, 16 accidents occurred near the intersection of US 2 and Bear Creek Road. Most of the accidents were due to improper or inattentive driving or wildlife on the road (MDT 2012). No data for crash rates on Bear Creek Road or Libby Creek Road are available.

3.21.3.2 NFS Road #278 (Bear Creek Road)

Bear Creek Road intersects US 2 at MP 39.7, 7.0 miles east of the Libby city limit boundary. It functions primarily as a recreational road, providing access to the KNF. The first 0.75 mile of Bear Creek Road is a two-way, two-lane roadway with a total width ranging from 18 to 20 feet. The remainder of the roadway is two-way, single-lane with a total width of about 14 feet. The first 9.5 miles is paved with hot mix asphalt, and the asphalt road surface is chip-sealed and in poor condition Bear Creek Road crosses Bear Creek at MP 9.5; the bridge across Bear Creek is 14 feet wide. The remainder of the road is a native (dirt) surface. The road is designed for speeds of 25 mph. The degree of intervisible turnouts is 50 percent; an intervisible turnout is an area designed to allow vehicles to pass and so spaced to provide visibility between the turnouts. The roadway geometry is curvilinear with various curves in several locations. The roadway profile is mountainous. The Bear Creek Road in its current alignment is owned by the Forest Service. The KNF holds easements for those segments that cross private land.

Table 170. US 2 Accident Data (MP 39.0 to MP 40.5).

Year	Total Number of Crashes	Total Number of Fatal Crashes	Total Number of Injury Crashes	Total Number of Property Damage Only Crashes
2007	5	0	4	1
2008	1	0	0	1
2009	8	0	2	6
2010	1	0	0	1
2011	1	0	0	1
Total	16	0	6	10

MP = milepost.
Source: MDT 2012.

Because the roadway is not an all-weather road (Stantus, pers. comm. 2006b), it is closed during spring frost break-up for vehicles weighing over 10,000 pounds. All types of vehicles can travel on the roadway except when mud and snow conditions limit use to 4-wheel drive (USDA Forest Service *et al.* 1992). There has been little maintenance to the roadway and several areas of the roadway have settled due to subsurface instability.

Yearly traffic volumes supplied by the KNF from 1986 through 1991 (Table 171) were used to develop traffic growth rates and peak hour traffic volumes. According to the KNF, the actual existing volumes may be lower than the provided volumes due to significant decreases in timber operations since 1991 (Lampton, pers. comm. 2006).

Table 171. Estimated Yearly Traffic on Bear Creek Road.

1986	1987	1988	1989	1990	1991
15,957	18,773	13,175	17,355	19,150	13,615

Source: Stantus 2006a.

3.21.3.3 NFS Road #231 (Libby Creek Road)

Libby Creek Road intersects US 2 at MP 42.0, 9.3 miles east of the Libby city limit boundary. It functions as a recreational road providing access to the KNF. Libby Creek Road has a two-way, two-lane width of 22 feet and a chip-seal paved surface for the first 0.5 mile. The road then narrows to a two-way, single-lane width varying from 14 to 16 feet with a gravel surface until the bridge at MP 9.2 (Lampton, pers. comm. 2006). This road segment is designed for speeds of 25 mph and the degree of intervisible turnouts is 75 percent. At MP 9.2 (intersection with Bear Creek Road) and proceeding until MP 10.6, the road changes to a two-way, single-lane width of 12 feet and maintains the gravel surface. This road segment is designed for speeds of 20 mph and the degree of intervisible turnouts is 50 percent. From MP 10.6 to the end of the road, the roadway surface is native and the two-way, single lane roadway width is 12 feet. This road segment is designed for speeds of 15 mph and there are no intervisible turnouts (USDA Forest Service *et al.* 1992). The roadway geometry is curvilinear with very sharp curves in several locations. The roadway profile is mountainous. The Forest Service does not post speed limits on the road.

Lincoln County owns three segments of the Libby Creek Road that would be used in all mine and transmission line alternatives: a 0.7-mile segment beginning at the northern intersection with US

2; a 2.8-mile segment from the intersection with the Bear Creek Road south to the intersection of NFS road #4779 near Howard Creek; and a 2.8-mile segment beginning at the southern intersection with US 2. The remainder of the Libby Creek Road is owed by the Forest Service. The KNF holds easements for those segments that cross private or State land.

The Libby Creek Road is not built to an all-weather standard and, like Bear Creek Road, is closed during spring frost break-up to vehicles weighing over 10,000 pounds. All vehicles can generally use the roadway except during snow and mud conditions when travel is limited to 4-wheel drive (USDA Forest Service *et al.* 1992). Some culverts and surfacing have been replaced in the last 5 years (Stantus, pers. comm. 2006b).

3.21.3.4 Other National Forest System Roads

The Forest Service manages all other National Forest System roads in the analysis area that would be used in the alternatives. Some roads on private and State lands would be used during transmission line construction and decommissioning. The access status of some National Forest System roads would be changed as a result of the wildlife mitigation. Table 28 and Table 29 provide a complete description of these road access changes.

3.21.4 Environmental Consequences

3.21.4.1 Congestion

3.21.4.1.1 Alternative 1 – No Mine

Without the proposed mine, traffic on US 2 from White Haven to Bear Creek Road would grow at an annual rate of 1.2 percent, increasing from a predicted 1,914 vehicles per day in 2010 to 2,401 vehicles in 2029. This would result in peak hour traffic of 288 vehicles per hour in 2010 and 361 vehicles per hour in 2029. For the entire 19-year period from 2010 to 2029, US 2 would function at LOS C in this two-lane section of the roadway, due to the limited passing opportunities and the percent of time vehicles spent following other vehicles. Between Libby and White Haven, traffic would grow at 1.2 percent annually with traffic increasing from 5,075 vehicles per day in 2010 to 6,370 vehicles per day in 2029. Peak hour traffic would be 760 vehicles per hour in 2010 and 960 vehicles per hour in 2029. This four-lane section would operate at LOS A through 2027.

The traffic on Bear Creek Road averaged 16,338 vehicles per year between 1986 and 1991 (Table 171). Assuming traffic on the Bear Creek Road increased at the same rate as traffic on US 2, average annual traffic would be 20,493 vehicles in 2010. Without the proposed mine, traffic would grow at an annual rate of 1.2 percent increasing to 25,707 vehicles per year in 2029. No improvements would be completed to Bear Creek Road under this alternative. A negligible increase in traffic volumes along the Bear Creek Road and NFS roads #4781 and #6210 would occur during ongoing activities at the Libby Adit.

Peak-hour traffic entering US 2 from Bear Creek Road would experience a LOS B through 2029. The increase in traffic also would not affect peak hour traffic turning left from US 2 onto Bear Creek Road. It would experience a LOS A during the entire 19-year period from 2010 to 2029.

3.21.4.1.2 Alternative 2 – MMC's Proposed Mine

The low volume of traffic generated by the proposed mine would not adversely affect the operation of US 2. The proposed mine would generate an additional 132 vehicles per day on US 2, including 52 trucks and six buses. US 2 would continue to function at LOS C during the peak hour period in the two-lane section during the entire 19-year period from 2010 to 2029. The additional mine-related traffic also would not affect the four-lane section of the roadway, which would still function at LOS A through 2027.

The US 2/Bear Creek Road intersection would remain at LOS B during operations with the addition of mine-related traffic to the existing traffic entering US 2 from Bear Creek Road. Peak hour traffic turning left from US 2 onto Bear Creek Road also would not experience a reduction in LOS due to the mine-related traffic and would still operate at a LOS A.

Traffic on Bear Creek Road (NFS road #278) would increase in all mine alternatives. Annual traffic would be about three times existing levels throughout the life of the mine (Table 172). To accommodate the increased traffic, about 10 miles of the Bear Creek Road (NFS road #278), from US 2 to the Bear Creek bridge, would be chip-and-seal paved and upgraded to 20 to 29 feet wide. Several short segments of the Bear Creek Road around the Little Cherry Creek Impoundment and Diversion Channel also would be realigned under this alternative. Reconstruction is anticipated to take 2 years. The reconstruction of Bear Creek Road would minimize future congestion because the roadway would be upgraded to a uniform width that would accommodate two-way traffic in separate lanes. When the mill ceased operations in the Closure Phase, traffic volumes would be substantially less than shown in Table 172.

Table 172. Estimated Traffic on Bear Creek Road (NFS road #278) with Mine, all Mine Alternatives.

Year	Estimated Annual Traffic without Mine (Vehicles per Year)	Estimated Mine Traffic (Vehicles per Year)	Estimated Traffic With Mine (Vehicles per Year)	% Increase
2010	20,493	48,048	68,541	234%
2015	21,753	48,048	69,801	221%
2020	23,090	48,048	71,138	208%
2025	24,509	48,048	72,557	196%
2029	25,707	48,048	73,755	187%

MMC would continue to plow and use the Libby Creek Road (NFS road #231) and the Upper Libby Creek Road (NFS road #2316) year-round during the 2-year evaluation program and the 1-year period during reconstruction of the Bear Creek Road. The use would increase traffic on the two roads, and would keep open roads previously closed in the winter. The addition of mine-related traffic to the existing traffic entering US 2 from Libby Creek Road in 2010 would not affect the LOS and would remain LOS B during 3-year period.

The Forest Service would require MMC to include the terms of road use in its amended Plan of Operations before using Libby Creek Road during mine evaluation and construction activities. The Plan of Operations would include the requirement for a monetary deposit for gravel replacement and conditions for dust control. Approved plan requirements for road use would be determined by the level of use anticipated by MMC.

Six roads currently open, Little Cherry Loop Road (NFS road #6212), a 1.6-mile long segment of Little Cherry Bear Creek Road (NFS road #5182), NFS road #8838, a 1-mile long segment of

Poorman Creek Road (NFS road #2317), 0.2 mile of NFS road #5170, and a 0.7-mile long segment of Ramsey Creek Road (NFS road #4781), would be gated and used for mine traffic only during operations. The gates on the Little Cherry Loop Road (NFS road #6212) and the Poorman Creek Road (NFS road #2317) would be near the intersection with the Bear Creek Road on the north end and the tailings impoundment permit area boundary on the south end. Gating the Little Cherry Loop Road (NFS road #6212) would restrict motorized access to NFS roads #5182 and #8838. The gate on the Poorman Creek Road (NFS road #2317) would be near its intersection with the Bear Creek Road south of Poorman Creek. Gating the Poorman Creek Road (NFS road #2317) would restrict motorized access to the Ramsey Creek Road (NFS road #4781) and NFS road #5170 (Figure 17).

At the end of operations, gates on formerly open roads would be removed and the roads would reopen to motorized access. An exception would be a segment of the Little Cherry Loop Road (NFS road #6212) that would be covered by the tailings impoundment and would no longer provide a loop between the Bear Creek Road. Traffic on the Bear Creek Road would increase over the long term due to the loss of the Little Cherry Loop Road beneath the impoundment and the anticipated improvements.

3.21.4.1.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Alternative 3 would have similar effects on congestion and level of service as Alternative 2. The US 2/Bear Creek Road intersection would remain at LOS B during operations with the addition of mine-related traffic to the existing traffic entering US 2 from Bear Creek Road. Creation of a supply staging area in Libby and consolidating shipments to the mine area would slightly reduce traffic from that estimated for Alternative 2 (Table 172).

The public and mine traffic would use the Bear Creek Road (NFS road #278) from US 2 to where a new Libby Plant Access Road would parallel it, in the center of the Poorman Impoundment Site near the intersection of NFS road #6201. MMC would surface the existing NFS road #278 (Bear Creek Road) from the junction with NFS road #6201 to NFS road #231 (Libby Creek Road) with 6 inches of gravel 16 feet wide. The Libby Plant Access road would be used solely for mine traffic except for two segments of the road where there would be mixed mine haul and public traffic (Figure 29). Mine haul traffic would be mine haul trucks carrying waste rock to the impoundment area from the mine adit and may exceed the 20-ton limit for vehicles on area highways. The bridge on NFS road #6212 across Poorman Creek would be removed during construction and the road south of Poorman Creek to the intersection of NFS road #278 would be decommissioned. A gate on the road would be installed near the tailings impoundment permit area boundary on the north end. Depending on timing of project construction, the KNF may need administrative access to NFS road #6212P to allow access to a gravel pit at the road's terminus. At the end of mine operations, the connection between the Bear Creek Road and the Libby Creek Road (NFS road #231) would exist via the new Libby Plant Access Road and the Poorman Creek Road (NFS road #2317). The bridge over Poorman creek on this new Libby Plant Access Road would remain for public access and use.

The Poorman Creek Road would remain open to motorized access from the intersection with the Bear Creek Road to its current closure location at the intersection of NFS road #2317B. A small parking area would provide parking for non-motorized access up Poorman Creek.

At the end of operations, gates on formerly open roads would be removed and the roads would reopen to motorized access. An exception would be a segment of the Little Cherry Loop Road

(NFS road #6212) that would be covered by the tailings impoundment and would no longer provide a loop between the Bear Creek Road. Traffic on the segment of the Bear Creek Road between Poorman and Bear creeks would increase over the long term due to the loss of the Little Cherry Loop Road beneath the impoundment. About 3.2 miles of the Ramsey Creek Road (NFS road #4781) would be barriered and closed to administrative use for grizzly bear mitigation in Alternative 3. This change would reduce administrative access to the Ramsey Creek drainage.

3.21.4.1.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Alternative 4 would have similar effects on congestion and level of service as Alternative 2. The public and mine traffic access for Bear Creek Road would be the same as described in Alternative 3. The US 2/Bear Creek Road intersection would remain at LOS B during operations with the addition of mine-related traffic to the existing traffic entering US 2 from Bear Creek Road.

The gates on the Little Cherry Loop Road (NFS road #6212) and the Poorman Creek Road (NFS road #2317) would be near the intersection with the Bear Creek Road on the north end and the tailings impoundment permit area boundary on the south end. Gating the Little Cherry Loop Road (NFS road #6212) would restrict motorized access to NFS roads #5182 and #8838.

The Poorman Creek Road would remain open to motorized access from the intersection with the Bear Creek Road to its current closure location at the intersection of NFS road #2317B. A small parking area would provide parking for non-motorized access up Poorman Creek.

At the end of operations, gates on formerly open roads would be removed and the roads would reopen to motorized access. An exception would be a segment of the Little Cherry Loop Road (NFS road #6212) that would be covered by the tailings impoundment and would no longer provide a loop between the Bear Creek Road. Traffic on the segment of the Bear Creek Road between Poorman and Bear creeks would increase over the long term due to the loss of the Little Cherry Loop Road beneath the impoundment. About 3.2 miles of the Ramsey Creek Road (NFS road #4781) would be barriered and closed to administrative use for grizzly bear mitigation in Alternative 4. This change would reduce administrative access to the Ramsey Creek drainage.

3.21.4.1.5 Alternative A – No Transmission Line

Without the traffic related to the transmission line initial construction and continued operations and maintenance, the LOS on US 2 and related roadways would operate at acceptable levels, similar to those experienced on US 2 without the mine-related traffic. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

3.21.4.1.6 All Transmission Line Alternatives

The traffic generated by the initial construction, continued operations and maintenance and final decommissioning of any of the transmission line alternatives would have no significant effect on the traffic congestion of the affected roadways and intersections due to the low volumes of traffic generated. Short, intermittent delays on US 2 would occur during transmission line stringing operations. Guard structures would be placed on either side of US 2 to prevent the line from failing across the highway. Similar delays would occur and similar procedures would be used on currently open NFS roads, such as NFS road #231 or #385, used in the construction of the transmission line. Similar short, intermittent delays on U.S. would occur during the initial months of construction of the Sedlak Park Substation Site. These delays would not adversely affect traffic congestion on US 2.

3.21.4.2 Safety

3.21.4.2.1 Alternative 1 – No Mine

By the end of 2010, between the eastern city limit of Libby to the town of White Haven, US 2 is projected to have experienced an estimated 7 accidents without mine traffic. For 2010, US 2 will have experienced 3 accidents from White Haven to Bear Creek Road. In 2029, the accidents between Libby and White Haven would increase to 9 accidents and 4 accidents between White Haven and Bear Creek Road. The increase in accidents would be due to the increase in traffic volumes during that same period.

3.21.4.2.2 Alternative 2 – MMC's Proposal

On US 2, the proposed mine would generate an additional 132 vehicles per day over the base traffic volume without the mine and would result in an additional 0.4 accidents per year from 2010 to 2029, for a total of 8 additional accidents over the 19-year life of the proposed mine. The increased number of accidents would be due to the increase in traffic volumes, would be short-term, and would return to a number without the mine at the end of the project.

The intersection of US 2 and Bear Creek Road meets current MDT sight distance requirements for left and right turning vehicles from Bear Creek Road onto US 2. The intersection also meets the stopping sight distance requirements for vehicles turning from US 2 onto Bear Creek Road. Turn lanes for eastbound US 2 traffic turning right onto Bear Creek Road and westbound US 2 traffic turning left onto Bear Creek Road would not be warranted based on the expected traffic volumes in 2010 or 2029. The Bear Creek Road is a public approach to US 2. MMC would evaluate the Bear Creek Road/US 2 and the Kootenai Business Park access road/US 2 intersections for the largest design vehicle and modify the intersections if the approach of either intersection did not meet the design requirements for that vehicle. The approach would be designed to maintain the transportation system level of service or safety in the analysis area.

On the Bear Creek Road and the Libby Creek Road, no accident data are available to calculate the anticipated number of accidents due to the increase in traffic from the proposed mine. On the Bear Creek Road, MMC would reconstruct the segment between US 2 and the Bear Creek bridge to a consistent two-lane width that is appropriate for two-way traffic to pass unobstructed. The minimal mine-related traffic on Libby Creek Road during the time period that Bear Creek Road was reconstructed would have no adverse effect on the safety of Libby Creek Road.

MMC would design the Bear Creek Road for speeds of 35 to 45 mph, an increase from the current design speed of 25 mph. Design exceptions for slower speeds may be needed on some curves. Mine Safety and Health Administration regulations (30 CFR 56, Subpart H) require that all mines establish and follow rules governing speed, right-of-way, direction of movement, and the use of headlights to assure appropriate visibility, and that equipment operating speeds be consistent with conditions of roadways, grades, clearance, visibility, traffic, and the type of equipment used. MMC would post warning signs for speed limits and other important road conditions and require all mine-related vehicles to follow all traffic control restrictions, such as speed. The effect of road improvements and higher speeds may lead to a slight increase in accidents. The minimal mine-related traffic on Libby Creek Road during the time period that Bear Creek Road was reconstructed would have no adverse effect on the safety of Libby Creek Road.

MMC would reconstruct the Bear Creek Road from US 2 to the Ramsey Access Road to a roadway width of 20 to 29 feet. MMC has not assessed if the easements across private land held by the Forest Service would allow for widening to the proposed width. Mine haul traffic and public traffic would share two segments of roads, a 2.5-mile segment of the Bear Creek Road between the Little Cherry Creek Impoundment Site to the Ramsey Access Road and a 0.6-mile segment of NFS road #2316 east of the Libby Adit Site (Figure 29). MMC's proposed widths would not safely accommodate mine haul traffic and public traffic. The Mine Safety and Health Administration (Mine Safety and Health Administration 1999) recommends a road width of 56 feet wide to accommodate joint-use traffic safely.

MMC would inspect the Bear Creek bridge for load capacity, but expects it would be sufficient for mine use. The bridge width, which is currently 14 feet, would be inconsistent with the width of the improved Bear Creek Road. Because mine traffic and public traffic would share the Bear Creek Road north of the Little Cherry Creek Impoundment, the narrow bridge width may lead to safety concerns. (See Alternative 3 for agency-mitigated measures to address these concerns.)

The Bear Creek Road between the intersection with Libby Creek Road and the new Ramsey Plant Access Road would not be reconstructed and would remain in its current unpaved condition.

3.21.4.2.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative and Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

These alternatives would have the same effect on the number of accidents on US 2 as Alternative 2. The roadway width would be upgraded to two 12-foot wide travel lanes and two shoulders of 1 foot, for a total width of 26 feet. Additional widening would be necessary on curves and short segments of new road would be needed. A reconstructed bridge at Bear Creek widened to 26 feet would be safer than the existing bridge. The new bridges would be long enough to convey a 100-year flow event, to comply with INFS standards and Forest Service guidance, such as fish passage or conveyance of adequate flows (USDA Forest Service 1995, 2008a).MMC would complete a preliminary and final design of the reconstructed road. If preliminary design indicates the reconstructed road would exceed the current right-of-way width across private land, MMC will make a reasonable effort during the Evaluation Phase to secure all necessary easements to accommodate the needed road right-of-way width.

Public and mine haul traffic would share 1.8 miles of road in Alternative 3 and 3.8 miles of road in Alternative 4 (Figure 38). The joint-use road segments would be widened to widths recommended by the Mine Safety and Health Administration (Mine Safety and Health Administration 1999). For a 16-foot wide haul vehicle, the road width would be 56 feet wide to safely accommodate joint-use traffic. All bridge would be reconstructed to a width compatible with the reconstructed width of the adjacent road segment. A wider road width would safely accommodate joint-use traffic.

In Alternative 3, MMC would surface the existing NFS road #278 (Bear Creek Road) from the junction with NFS road #6201 to NFS road #231 (Libby Creek Road) with 6 inches of gravel 16 feet wide (Figure 29). Similarly, MMC would surface the Bear Creek Road from new Libby Plant access road to the Libby Creek Road in Alternative 4 (Figure 38). This surfacing would ensure the safe transition from the improved section north of the new Libby Plant Access Road and the unimproved section to the Libby Creek Road.

Modifications to the intersection of US 2 and the Bear Creek Road and to the intersection of US 2 and the Kootenai Business Park access road would be required if the approach did not meet the design requirements for the largest design vehicle. Any modification to US 2 would require the approval of the MDT. This mitigation would maintain the transportation system level of service and safety in the analysis area.

Before initiating the Construction Phase, MMC would submit a traffic impact study report to the agencies and MDT that address the requirements of MDT's System Impact Action Process (Montana Department of Transportation 2007). The study would identify measures necessary to maintain safe public roads and highways and acceptable operational levels of service.

3.21.4.2.4 Effectiveness of Agencies' Mitigation Measures

Widening roads, culverts, and bridges to an appropriate width would be effective in minimizing conflict between mine traffic and other road users. Graveling a section of the existing NFS road #278 (Bear Creek Road) would be effective in maintenance requirements on the Bear Creek Road. Proper design and implementation of any necessary improvements of US 2 and its intersections that would be identified in the traffic impact study would be effective in maintaining the transportation system level of service and safety on US 2. Developing and implementing a transportation plan and a road management plan would be effective in minimizing project-related traffic and indirect environmental effects.

3.21.4.2.5 Alternative A – No Transmission Line

Without the traffic related to the initial construction and continued operations and maintenance of the transmission line, substation and loop line, the safety on US 2 and related roadways would be similar to those experienced on US 2 without the mine-related traffic. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

3.21.4.2.6 All Transmission Line Alternatives

None of transmission line alternatives, which include the Sedlak Park Substation and loop line, would result in adverse impacts on the safety of the transportation network due to the minimal volume of traffic that would be generated by the transmission line construction, continued operations and maintenance, and final decommissioning. The approach to the Sedlak Park Substation would be designed not to affect the transportation system level of service or safety in the analysis area.

3.21.4.3 Cumulative Effects

The KNF's Miller-West Fisher Vegetation Management Project will consist of vegetative treatments including timber harvest, slash treatment, site preparation, prescribed burning, tree planting, precommercial thinning, construction of new roads, road storage and decommissioning activities, road reconstruction, and implementation of BMPs. Depending on the timing of these activities and construction of the transmission line, traffic volumes may be cumulatively greater in the Miller Creek and West Fisher Creek drainages. Many of the other reasonably foreseeable actions would use the same roads as the Montanore Project. The reasonably foreseeable actions and the Montanore Project would cumulatively increase traffic volumes near access roads. The additional traffic would not adversely affect the level of service on US 2 or lead to adverse congestion.

3.21.4.4 Regulatory/Forest Plan Consistency

All action alternatives would be consistent with the KFP standards regarding roads, regulations governing the administration of the Forest Transportation System (36 CFR 212), and with the Forest Service Transportation Administrative Policy FSM Chapter 7700 (2001). All roads to be built for the project would be constructed, maintained, and decommissioned to minimize adverse environmental impact, in accordance with the Forest Service locatable minerals regulations (36 CFR 228.8). Only the minimum number of roads would be constructed to the minimum standard necessary. Unneeded roads used during construction would be decommissioned. Compliance with 36 CFR 228.8(f) regarding roads management is discussed in section 3.6.4.11.4 *National Forest Management Act/Kootenai Forest Plan* (RF-2 through RF-5), beginning on page 453.

3.21.4.5 Irreversible and Irretrievable Commitments

All mine alternatives would increase traffic on the roadways, thereby increasing the fuel used by vehicles beyond the no-mine alternative. Fuel is a non-renewable resource; thus, an increase in traffic related to the mine alternative would result in an irreversible commitment of resources. All mine alternatives would increase the number of accidents during the mine's operation and closure. Increased accidents would be an irreversible commitment of resources.

3.21.4.6 Short-term Uses and Long-term Productivity

During the mine's and transmission line construction, operation and closure, increased traffic congestion and accidents could occur on roads and highways used in the project, and would cease at the end of the closure period.

3.21.4.7 Unavoidable Adverse Environmental Effects

During the mine's operation and closure, traffic congestion and accidents would occur on roads and highways used in the project. Increased congestion and accidents would cease at the end of the closure period.

3.22 Vegetation

3.22.1 Vegetation Communities

3.22.1.1 Regulatory Framework

The Organic Administration Act authorizes the Forest Service to regulate the occupancy and use of National Forest System lands. The Forest Service's locatable minerals regulations are promulgated at 36 CFR 228, Subpart A. The regulations apply to operations conducted under the U.S. mining laws as they affect surface resources on National Forest System lands under the jurisdiction of the Secretary of Agriculture. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources.

The National Forest Management Act requires the Secretary of Agriculture to promulgate regulations specifying guidelines for land management plans that "provide for the diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet overall multiple-use objectives…" The "specific land area" (scale) for providing diversity is established in the framework as the area covered by the Forest Plan, or the entire KNF. One of the KFP goals is to "maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species… and in sufficient quality and quantity to maintain habitat diversity representative of existing conditions" (II-1 #7). Riparian areas within the KNF are managed according to RMOs established in the INFS. The RMOs and RHCAs are discussed in section 3.6, *Aquatic Life and Fisheries*.

Sensitive species are designated by the Regional Forester (FSM 2670.5). FSM 2672.42 directs the Forest Service to conduct a biological evaluation (BE) to analyze impacts on sensitive species. The sensitive species analysis in this document meets the requirements for a BE as outlined in FSM 2672.42. FSM 2670.22 requires that the Forest Service develop and implement management practices to ensure that sensitive species do not become threatened or endangered because of Forest Service actions and maintain viable populations of all native and desired nonnative wildlife, fish, and plant species in habitats distributed throughout their geographic range on National Forest System lands. Any decision on the Montanore Project cannot result in loss of sensitive species viability or create significant trends toward federal listing (FSM 2670.32). Sensitive plant species identified within the analysis area are the northern beechfern or the crenulated moonwort.

For lands affected by the transmission line, the MFSA directs the DEQ to approve a facility if, in conjunction with other findings, the DEQ finds and determines that the facility would minimize adverse environmental impacts, considering the state of available technology and the nature and economics of the various alternatives. If approved, DEQ would require that disturbances from the transmission line would be reclaimed to standards set by administrative rule (ARM 17.20.1902 (10)(b)).

The MMRA requires that lands affected by mining must meet the post-mine land uses. The DEQ evaluates in its environmental documents whether the revegetation plans for mine facilities would adequately meet the post-mine land uses.

3.22.1.2 Analysis Area and Methods

3.22.1.2.1 Analysis Area

The analysis area consists of all areas that would be disturbed by construction of the mine, transmission line, substation and loop line under any alternative (Figure 85) and streams that may be indirectly affected by changes in hydrology. The vegetation at the Libby Loadout has been completely disturbed and the loadout is not discussed further.

3.22.1.2.2 Impact Analysis Methods

Vegetation mapping for the analysis area was obtained from baseline inventories (Western Resource Development Corp. 1989d, 1989e; Westech 2005d, 2005e; Geomatrix 2009b; Hydrometrics, Inc. in MMI 2005a). Coniferous forest includes old growth forest. Old growth and previously harvested coniferous forest mapping for National Forest System lands was provided by the KNF as GIS data layers. Old growth and previously harvested coniferous forest on non-National Forest System lands was mapped based on aerial photography and field verified by KNF biologists. Where they overlapped, community types were determined in the following priority order: wetland/riparian, old growth forest, which was mapped as coniferous forest, and previously harvested coniferous forest. All areas that were not previously harvested coniferous forest or wetland/riparian were mapped as coniferous forest vegetation community.

Impacts of the mine alternatives on vegetation communities were determined by calculating the number of acres that would be disturbed. The mine reclamation plans of the alternatives also were compared. The analysis of transmission line, substation and loop line effects calculated the total acreage within the clearing width of each alternative. Actual acreage cleared would be less and would depend on tree height, slope, and line clearance above the ground. Vegetation communities affected by road construction for transmission line access were calculated for each alternative. For analysis purposes, it is assumed that minor disturbances of vegetation from staging and yarding areas and stringing, and tensioning sites would occur within the clearing width.

Because mine and adit dewatering, the pumpback well system operation around the impoundment, and other project activities may result in streamflow changes, indirect effects on riparian vegetation were assessed. Representative cross sections at important aquatic habitat locations were selected on Libby Creek (1 mile upstream of Little Cherry Creek), East Fork Rock Creek (1 mile upstream of the confluence with the West Fork Rock Creek), and East Fork Bull River (at the confluence with Isabella Creek) to collect data on vegetation communities, stream cross section widths, and velocity. Using baseline data and changes in streamflow predicted from the 3D groundwater model, changes in wetted perimeter were predicted (Section 3.11.4 *Surface Water Hydrology*) to assess effects on riparian vegetation.

3.22.1.3 Affected Environment

Vegetation communities have developed across the landscape in response to climate, disturbance, and other environmental factors. Historically, dominant forest species were a mix of long-lived species such as white pine, western larch, ponderosa pine, and whitebark pine and short-lived species such as lodgepole pine, and alpine fir. Currently, the forest stands in the analysis area are dominated by Douglas-fir, lodgepole pine, alpine fir, grand fir, and western hemlock, with lodgepole pine abundant on the higher-elevation, steeper slopes as a result of stand-replacing fire in the late 1800s and 1910. Changes in composition are due primarily to past management activities such as timber harvesting and fire suppression (USDA Forest Service 2001). Three dominant vegetation communities, mature coniferous forest; previously harvested young coniferous forest; and wetlands including riparian areas, are found in the analysis area; a total of 410 plant species were observed (Westech 2005d). Vegetation communities in the analysis area are shown in Figure 85 and summarized below.

3.22.1.3.1 Coniferous Forest

About 50 percent of the analysis area is composed of mature coniferous forest vegetation communities including unlogged areas. Mature coniferous forests have large economic potential associated with timber harvesting and provide habitat for a variety of wildlife and plant species. Timber harvesting generally occurs mainly where the dominant tree species are lodgepole pine, western hemlock, western redcedar, grand fir, Engelmann spruce, Douglas-fir, and western larch (Westech 2005d).

Stand structure within the KNF varies from new growth to old growth managed areas. Within the mature coniferous forest vegetation communities, the KNF has identified stands of old growth that are managed to maintain diversity and habitat for wildlife and plant species. Old growth ecosystems and the habitat they provide for wildlife species are described in section 3.22.2*, Old Growth Ecosystems*.

The KNF has established Vegetative Response Units (VRUs) to aggregate lands having similar capabilities and management potential and to assist the KNF in preparation of site-specific prescriptions. The VRU system can help managers interpret vegetation community response to management or natural disturbance and project future landscapes based on current conditions. The major VRUs in the analysis area are VRU5S and VRU5N, which are moderately cool and moist ecosystems (USDA Forest Service 1999c).

3.22.1.3.2 Previously Harvested Coniferous Forest

The previously harvested coniferous forest vegetation community includes all areas where trees were harvested, both intermediate harvest that maintained the existing stand or regeneration harvest that initiated a new stand. Most previously harvested areas have well-established conifer regeneration with western larch, western white pine, grand fir, and lodgepole pine. Higher-elevation areas are dominated by lodgepole pine, Engelmann spruce and subalpine fir; while mid to lower-elevation areas are dominated by western larch, Douglas-fir, lodgepole pine, and ponderosa pine. As with the mature coniferous forest vegetation type, understory composition and cover varies considerably with site conditions, elevation, tree cover, and stand age. In younger previously harvested coniferous forest areas, more introduced species and noxious weeds are present than in older harvested areas (Westech 2005d).

3.22.1.3.3 Wetlands and Riparian Areas

Within the analysis area, wetlands and riparian vegetation communities are present along most streams and rivers. Wetlands are also found in depressions at both tailings impoundment sites, and along the transmission line alternatives. Wetlands and wetland vegetation are discussed in section 3.23, *Wetlands and Other Waters of the U.S*.

Riparian areas along Fisher River, Libby Creek, and Miller Creek support several riparian/wetland vegetation communities including riparian coniferous forest, cottonwood forest, shrub thickets, and herbaceous fringes. Riparian coniferous forest includes western redcedar, western hemlock, and Engelmann spruce with understory species of ladyfern, devil's club, oakfern, common horsetail, clintonia, common snowberry, thimbleberry, Sitka alder, and Rocky

Mountain maple. Riparian cottonwood forests are present along Fisher River, where black cottonwood, Douglas-fir, and ponderosa pine are the dominant tree species with common snowberry, alder buckthorn, willow, and Wood's rose making up the understory. Other herbaceous species include introduced reed canarygrass, native fowl bluegrass, and introduced common tansy, a noxious weed. Shrub thickets are present along the Fisher River, Miller Creek, and upper elevation streams with stands of Douglas spirea, thinleaf or Sitka alder, willow, and alder buckthorn.

Riparian vegetation along the banks of Libby Creek at the cross section is mostly dominated by black cottonwood, Douglas-fir, spruce, Western red cedar, alder, and willow. At the cross sections of the East Fork Bull River and East Fork Rock Creek, the vegetation is dominated by Western red cedar, mountain maple, black cottonwood, Western hemlock, Pacific yew, and grand fir with Devil's club in the understory. These streams are fairly entrenched and are characterized by medium to large cobble.

3.22.1.3.4 Other Vegetation Communities

Other vegetation communities in the analysis area are present in small quantities (Westech 2005d). Mapping of the vegetation communities has been consolidated with more dominant vegetation communities in the analysis area. These small vegetation communities are described below.

The shrub-field vegetation community is found in avalanche chutes where rock outcrops, talus, or scree are present. The shrub-fields are periodically disturbed by avalanche and have low cover and low tree density. Shrub species include Rocky Mountain maple, Sitka alder, common snowberry, white spirea, pachistima, serviceberry, and bristly Nootka rose. For analysis purposes, the shrub-field vegetation community is included in the coniferous forest community.

The grassland community is found on steep convex ridges or slopes. Dominant grass species are natives including Idaho fescue, purple reedgrass, and elk sedge. Other common native herbaceous species are clubmoss, fescue sandwort, yellow buckwheat, Sandberg's lomatium, Alberta penstemon, and western groundsel. For analysis purposes, the grassland community is included in the previously harvested coniferous forest community.

The Libby Adit Site, which is private land, was revegetated, reclaimed, and subsequently has been redisturbed by MMC. The disturbed mining area is dominated by introduced forbs such as birdsfoot trefoil and Dutch clover. Grasses such as introduced red fescue and native big bluegrass also are present. Some native forbs and noxious weeds such as spotted knapweed have established as well as some native tree species. For analysis purposes, the area disturbed at the Libby Adit Site is included in the previously harvested coniferous forest community.

3.22.1.3.5 Agricultural Land

Agricultural land used for livestock grazing is located along the Fisher River and along the Bear Creek Access Road. Dominant species include introduced timothy, Kentucky bluegrass, orchard grass, white Dutch clover, and red clover. For purposes of analysis, agricultural land areas are combined with previously harvested coniferous forest community.

3.22.1.4 Environmental Consequences

3.22.1.4.1 Alternative 1 – No Mine

The No Mine Alternative would not remove or affect any vegetation communities or individual species. Monitoring wells installed as part of the baseline monitoring would be removed and the area reclaimed. Disturbances on private land at the Libby Adit Site would remain until reclaimed in accordance with existing permits and approvals. Introduced species would continue to increase from current disturbance areas.

3.22.1.4.2 Alternative 2 – MMC's Proposed Mine

Alternative 2 would result in the removal and loss of vegetation communities on up to 2,582 acres during mine operations (Table 173). The mature coniferous forests vegetation community would be most affected, with up to 1,617 acres disturbed. The mature coniferous forest vegetation communities include old growth stands, which are discussed in section 3.22.2, *Old Growth Ecosystems*. Previously harvested coniferous forest would be the second largest vegetation community impacted, with a disturbance of 925 acres. About 40 acres of riparian and wetland areas would be affected by Alternative 2. Alternative 2 would affect more mature coniferous forest communities and riparian areas than the other alternatives. Effects on other vegetation communities would be minor. Indirect effect on riparian vegetation along Libby Creek, East Fork Bull River, and East Fork Rock Creek would be negligible. The change in wetted perimeter would be greatest during the post-closure (year 38) with a 26 percent change in wetted perimeter on East Fork Bull River and a 9 percent change in wetted perimeter on East Fork Rock Creek. With mitigation, no detectible change in wetted perimeter is expected on Libby Creek. The species that occur along these streams are mostly woody and have a wide moisture tolerance, some of which can be found in uplands with a similar or higher frequency as in riparian zones. Although cottonwood and willow have greater soil moisture requirements, the changes in wetted perimeter would occur during low flow, which would be a small percentage of the growing season during most years. During dry years, the low flows and reduction in wetted perimeter may extend for a longer portion of the growing season and cause stress and possibly dieback in cottonwoods and willows.

Table 173. Vegetation Communities within Mine Alternative Disturbance Areas.

Vegetation Community	Alternative 2 MMC's Proposed Mine	Alternative 3 Agency Mitigated Poorman Impoundment Alternative	Alternative 4 Agency Mitigated Little Cherry Creek Impoundment Alternative
Mature Coniferous Forest	1,617	865	1,143
Previously Harvested Coniferous Forest	925	683	740
Wetland/Riparian Areas	40	17	41
Total	2,582	1,565	1,924

All units are acres, rounded to the nearest acre.
Source: GIS analysis by ERO Resources Corp. using vegetation mapping in Westech 2005d.

Areas in Alternative 2 that require vegetation clearing and removal would be subject to an overall loss of biodiversity and a change in species composition during mine operations. Reclamation would re-establish plant communities but the biodiversity would be less, introduced species would be more common, species composition would not be the same, and timber production would be lost until the seral forest re-established after several decades. Westech (2005d) documented 410 different plant species in the analysis area. After reclamation of mine disturbances, a forest can take many years to re-establish a community with a diversity of plants similar to but less than the original plant community. Competitive introduced species may limit the ability of native grasses and especially forbs to re-establish after the disturbance. A loss of timber production on 1,102 acres of National Forest System lands suitable for timber production and 278 acres of private lands would occur throughout mining (Table 174). The loss would exist until timber regenerated and reached merchantable size. The tailings impoundment areas, which would disturb about 600 acres in each mine alternative, would be managed for mineral development following operations, and would no longer be managed for timber production. The area covered by asphalt and gravel by widening the Bear Creek Road would not be returned to pre-mine timber production.

Table 174. Lands Suitable for Timber Production within Mine Alternative Disturbance Areas.

Type	Alternative 2 MMC's Proposed Mine	Alternative 3 Agency Mitigated Poorman Impoundment Alternative	Alternative 4 Agency Mitigated Little Cherry Creek Impoundment Alternative
National Forest System Lands in Management Areas Suitable for Timber Harvest	1,102	1,016	813
Private Lands	278	23	268
Total	1,380	1,040	1,081

All units are acres, rounded to the nearest acre.
Source: GIS analysis by ERO Resources Corp. using KNF MA mapping and vegetation mapping in Westech 2005d.

The LAD Areas would experience a change in species composition during water application and may change again after water application was discontinued. If not managed properly, the LAD Areas may become dominated by species that favor seasonally saturated conditions, especially introduced species.

Interim reclamation would be used to revegetate disturbances from activities such as road cut-and-fill slopes and other temporary disturbances. In these locations, vegetation cover would return more quickly than those disturbed by mine operations. Some of the species in the interim mixture are introduced annual species. Upon completion of mining, disturbed areas would be reclaimed and revegetated. MMC's reclamation goal is to establish a post-mining environment comparable with existing conditions. The reclamation plan includes areas designated for reforestation, shrubs, or grasslands.

The permanent seed mix for Alternative 2 would be dominated by native species but quick establishing, more aggressive, non-native annual species are included in the seed mix. Over the long-term, reclaimed areas would likely have fewer native species than existing communities. MMC's monitoring plan, 3 consecutive years of revegetation success would be achieved before bond release would be requested. Loss of native species and some increase in introduced species is an unavoidable impact of allowing the mine disturbance.

3.22.1.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Alternative 3 would disturb up to 1,565 acres of vegetation (Table 173). The largest effect would be to the previously harvested coniferous forest vegetation communities (683 acres) and mature coniferous forest vegetation communities (865 acres). The impact on riparian and wetland areas would be about 17 acres and effects on other vegetation communities would be a small percentage of the disturbance. Effects on vegetation communities would be about 1,017 acres less than Alternative 2 because of a smaller Poorman Impoundment disturbance area. A loss of timber production on 1,016 acres of National Forest System lands suitable for timber production and 23 acres of private lands would occur throughout mining (Table 174). The loss of biodiversity, increase in introduced species, change in species composition, and loss of timber production on disturbed lands until forest regeneration would be similar to Alternative 2. Changes to MMC's reclamation plan, such as longer revegetation monitoring, elimination of non-native species and modification of soil salvage, handling, and replacement would facilitate revegetation of disturbed areas, minimize introduced species, and ensure long-term reclamation success. Indirect effects on riparian vegetation would be the same as Alternative 2.

3.22.1.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Alternative 4 would disturb up to 1,924 acres of vegetation, including 1,143 acres of coniferous forests and 740 acres of previously harvested coniferous forest (Table 173). The impact on riparian and wetland areas would be about 41 acres. Effects on vegetation communities would be about 696 acres less than Alternative 2 because LAD Areas would not be used to treat excess water and the disturbance surrounding the Little Cherry Creek Impoundment would be less. A loss of timber production on 813 acres of National Forest System lands suitable for timber production and 268 acres of private lands would occur throughout mining (Table 174). Effects, including loss of biodiversity, an increase in introduced species, and a change in species composition, would be similar to Alternative 2. Indirect effects on riparian vegetation would be the same as Alternative 2.

3.22.1.4.5 Alternative A – No Transmission Line

In Alternative A, the transmission line, substation, and loop line for the Montanore Project would not be built. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

3.22.1.4.6 Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

Alternative B would have the least effect on vegetation communities compared to the other transmission line alternatives because of a narrower clearing width (150 feet compared to 200 feet). The mature coniferous forest vegetation communities would be most affected by Alternative B. About 136 acres of mature coniferous forests, 133 acres of previously harvested coniferous forest, and 28 acres of wetland and riparian areas could be cleared (Table 175). Actual clearing would likely be less than that shown in Table 175 depending on tree height, slope, and line distance above the ground. Construction of new access roads for transmission line installation and maintenance are estimated to affect about 10 acres of mature coniferous forest, 5 acres of previously harvested coniferous forest, and less than 1 acre of wetland and riparian areas. A loss of timber production on 81 acres of National Forest System lands suitable for timber production and 135 acres of private lands would occur throughout the project until the transmission line was decommissioned and timber reached merchantable size (Table 176).

Table 175. Vegetation Communities along Transmission Line Alternatives.

Type†	Alternative B – North Miller Creek	Alternative C-R – Modified North Miller Creek	Alternative D-R – Miller Creek	Alternative E-R – West Fisher Creek
Transmission Line Clearing Area				
Coniferous Forest	136	166	182	93
Previously Harvested Coniferous Forest	133	136	131	235
Wetland/Riparian	28	15	18	35
Subtotal	297	317	331	363
Areas Disturbed by New or Upgraded Roads				
Coniferous Forest	10	2	3	2
Previously Harvested Coniferous Forest	5	1	1	2
Wetland/Riparian	1	<1	<1	0
Subtotal	16	3	4	4
Sedlak Park Substation and Loop Line				
Coniferous Forest	<1	<1	<1	<1
Previously Harvested Coniferous Forest	4	4	4	4
Subtotal	4	4	4	4
Total	317	323	338	365

All units are acres, rounded to the nearest acre.
†Acreage is based on a 150-foot clearing width for monopoles (Alternative B) and 200-foot width for H-frame structures (other alternatives except for a short segment of the West Fisher Creek Alternative that has monopoles). Actual acreage cleared would be less than listed and would depend on tree height, slope, and line clearance above the ground.
Source: GIS analysis by ERO Resources Corp. using KNF data, and vegetation mapping in Westech 2005d and MMI 2005b.

In 2003, Plum Creek sold a conservation easement (Thompson-Fisher Conservation Easement) to the FWP on 142,000 acres in northwest Montana, some of it within the analysis area (Figure 78). The conservation easement was partially funded by the Forest Legacy Program for the purpose of preventing the land from being converted to non-forest uses. One of the stated purposes of the conservation easement is to “preserve and protect in perpetuity the right to practice commercial forest and resource management.” Vegetation communities within the area covered by conservation are shown in Table 176. MMC did not propose to mitigation for the loss of timber production on lands covered by the conservation easement.

All disturbed areas would be interim seeded with native and introduced annual grass and native shrub species when construction of the transmission line and loop line was completed. Areas where trees would be trimmed, but otherwise not disturbed, would be allowed to establish naturally as grassland or shrubland. In accordance with BPA's health and safety policy, vegetation would be prevented from growing in the Sedlak Park Substation or within 5 feet of the substation fence. Within and outside the 100-foot right of way and within the 300-foot clearing width of the substation loop line, trees that pose a risk of falling on the transmission line would be cleared over the life of the line. Roads opened or constructed for transmission line access would be closed after transmission line construction was completed. The road surface would be reseeded as an interim reclamation measure designed to stabilize the surface. Where soil was salvaged from new roads, the road surface would be covered with soil and then reseeded. The new road prism would remain during transmission line operations. Introduced species would increase during mine life from the disturbance as well as from introduced species in the interim seed mix.

The BPA would clear all trees from its proposed 4-acre Sedlak Park Substation, including the access road between US 2 and the substation. It also would clear the woody vegetation within the 300-foot-wide right-of-way for the loop line that would connect the substation to the Noxon-Libby transmission line, in order to construct, operate, and maintain the substation and loop line. When the transmission line was decommissioned, the BPA would dismantle the substation, remove the loop line, and revegetate the area assuming it had no need for the facilities.

During the final Closure Phase following mining, the transmission line would be removed, roads recontoured to match existing topography, trees along the line allowed to grow, and all disturbed areas revegetated. Grassland and shrub communities would be the quickest to establish; the coniferous forest community and riparian forest would take many years to establish because many species are relatively slow growing.

3.22.1.4.7 Alternative C-R – Modified North Miller Creek Transmission Line Alternative

The use of a 200-foot clearing width for wooden H-frame structures for Alternative C-R would result in greater vegetation disturbance than Alternative B. About 166 acres of coniferous forest, 136 acres of previously harvested coniferous forest, and 15 acres of wetland/riparian areas would be cleared and would remain cleared over the life of the transmission line (Table 175). In Alternatives C-R, D-R, and E-R, a Vegetation Clearing Plan would be developed to minimize vegetation clearing in sensitive areas, such as RHCAs. Use of a helicopter to clear timber and construct structures in areas near core grizzly bear habitat would minimize effects on vegetation communities in these areas. Road construction would affect about 2 acres of mature coniferous forest, about 1 acre of previously harvested coniferous forest, and less than 1 acre of wetlands, and riparian areas. Timber production would be eliminated on 141 acres of National Forest System lands suitable for timber production and on 117 acres of private lands until the transmission line was decommissioned and timber reached merchantable size (Table 176). MMC would convey a conservation easement to the FWP on up to 91 acres (Table 176) of private land adjacent to the Thompson/Fisher conservation easement that have similar conservation values. Acquired lands or easements would be added to the existing conservation easement.

Table 176. Vegetation Communities along Transmission Line Alternatives Covered by Thompson-Fisher Conservation Easement.

Type	Alternative B – North Miller Creek		Alternative C-R – Modified North Miller Creek		Alternative D-R – Miller Creek		Alternative E-R – West Fisher Creek	
	Total	Covered by Thompson-Fisher Conservation Easement	Total	Covered by Thompson-Fisher Conservation Easement	Total	Covered by Thompson-Fisher Conservation Easement	Total	Covered by Thompson-Fisher Conservation Easement
National Forest System Lands in Management Areas Suitable for Timber Harvest	81	0	141	0	173	0	182	0
Private Lands	135	104	117	91	117	91	169	94
Total	216	104	258	91	290	91	350	94

All units are acres, rounded to the nearest acre.
†Acreage is based on a 150-foot clearing width for monopoles (Alternative B) and 200-foot width for H-frame structures (other alternatives except for a short segment of the West Fisher Creek Alternative that has monopoles). Actual acreage cleared would be less than listed and would depend on tree height, slope, and line clearance above the ground.
Source: GIS analysis by ERO Resources Corp. using KNF and FWP data, and vegetation mapping in Westech 2005d and MMI 2005b.

New roads on National Forest System lands would be placed into intermittent stored service by using a variety of treatment methods after transmission line construction was completed. Trees would be planted in all areas where trees were removed for the construction of the transmission line including access roads and other disturbances such as line stringing and tensioning sites, slash burn piles, and construction pads. Trees would be planted at a density such that at the end of 5 years the approximate stand density of the adjacent forest would be attained at maturity. This standard would not apply to roads placed in intermittent stored service, but would apply when the roads would be decommissioned after the transmission line was restored. Planting trees in disturbances would require less time for trees to become established, would better match surrounding landscape features, and would meet wildlife and density recommendations provided by the agencies.

Effects, including loss of biodiversity, an increase in introduced species, a change in species composition, and timber production on disturbed lands, would be similar to but less than mine Alternatives 2, 3, and 4, and similar to transmission line Alternatives B and D-R, and E-R.

3.22.1.4.8 Alternative D-R – Miller Creek Transmission Line Alternative

Alternative D-R, with a clearing width of 200 feet would affect up to about 182 acres of mature coniferous forest and 131 acres of previously harvested coniferous forest, and about 18 acres of wetland/riparian areas (Table 175). Road construction would affect about 3 acres of mature coniferous forest, about 1 acre of previously harvested coniferous forest, and less than 1 acre of wetlands and riparian areas. Timber production would be eliminated on 173 acres of National Forest System lands suitable for timber production and on 117 acres of private lands until the transmission line was decommissioned and timber reached merchantable size (Table 176). MMC would convey a conservation easement to the FWP on up to 91 acres (Table 176) of private land adjacent to the Thompson/Fisher conservation easement that have similar conservation values that would be added to the existing conservation easement. Reclamation and transmission line decommissioning at the end of mining operations would be the same as Alternative C-R.

Effects, including loss of biodiversity, an increase in introduced species, a change in species composition, and timber production on disturbed lands, would be similar to but less than mine Alternatives 2, 3, and 4, and similar to transmission line Alternatives B, C-R, and E-R.

3.22.1.4.9 Alternative E-R – West Fisher Creek Transmission Line Alternative

Alternative E-R would include tree clearing widths of 150 to 200 feet, depending on location. Clearing could affect about 93 acres of mature coniferous forest and 35 acres of wetland/riparian vegetation over the life of the transmission line. This alternative would make the best use of previously harvested coniferous forest (235 acres) to reduce the amount of new tree clearing. Road construction would disturb about 2 acres of coniferous forest and 2 acres of previously harvested coniferous forest. Timber production would be eliminated on 182 acres of National Forest System lands suitable for timber production and on 169 acres of private lands until the transmission line was decommissioned and timber reached merchantable size (Table 176). MMC would convey a conservation easement to the FWP on up to 94 acres (Table 176) of private land adjacent to the Thompson/Fisher conservation easement that have similar conservation values that would be added to the existing conservation easement. Reclamation at the end mining operations would be similar to Alternatives B, C-R, and D-R.

Effects, including loss of biodiversity, increase in introduced species, a change in species composition, and timber production on disturbed lands, would be similar to but less than mine Alternatives 2, 3, and 4, and similar to transmission line Alternatives B, C-R, and D-R.

3.22.1.4.10 Effectiveness of Agencies' Proposed Mitigation

Changes to MMC's reclamation plan, such as longer revegetation monitoring, elimination of non-native species and modification of soil salvage, handling, and replacement would be effective in facilitating revegetation of disturbed areas, minimizing introduced species, and ensuring long-term reclamation success. Revegetation success and recovery time of affected vegetation communities would depend on reclamation stage (interim or post-closure), vegetation community type, proper implementation, and environmental factors such as climate and soil conditions. Implementation of the agencies' Weed Control Plan would reduce impacts on native vegetation caused by increased weed infestation due to disturbance caused by the proposed action and its alternatives. The reclamation monitoring plan in Appendix C describes measures that would be implemented to assess the effectiveness of reclamation and actions that would be taken if reclamation success criteria were not met. MMC's bond would not be released unless the specified reclamation objectives were met.

Implementation of the Vegetation Removal and Disposition Plan would be effective in reducing impacts on vegetation from transmission line construction by minimizing clearing of trees and destruction of ground cover through the use of monopoles, where appropriate, and other measures.

3.22.1.4.11 Cumulative Effects

Past actions, particularly timber harvest, road construction, wildfires, and fire suppression activities, have altered the vegetation communities in the analysis area. Vegetation cover and diversity in disturbed areas have decreased. Disturbances have increased the distribution of noxious weeds and other introduced species. In the areas surrounding the proposed Montanore Project, several projects would contribute to the cumulative effect on vegetation communities such as the Libby Creek Ventures Drilling Plan and the Miller-West Fisher Vegetation Management Project. These projects would result in various degrees of vegetation clearing, disturbance, and subsequent revegetation. The primary effects would include an incremental change in species composition and seral stage from converting mature forests to an early successional stage or to grasslands and shrubland. These changes would cumulatively affect species biodiversity and productivity in the analysis area.

3.22.1.4.12 Regulatory/Forest Plan Consistency

3.22.1.4.13 Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8 to minimize adverse environmental impacts. MMC did not propose to implement feasible measures to minimize the disturbance area, maximize reclamation success, or minimize vegetation clearing. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would incorporate additional feasible and practicable measures to minimize adverse environmental impacts. These measures include minimizing the disturbance area of Alternatives 3 and 4, developing and implementing a final Road Management Plan and a Vegetation Removal and Disposition Plan; increasing the salvage and replacement of suitable soil materials for reclamation; using primarily

native species in revegetation; and salvaging disturbed wetland soils for use in constructing new wetlands.

All alternatives would comply with the KFP regarding vegetation communities. Under the proposed KFP amendment that would be implemented with each action alternative, the operating permit areas for the mine facilities and much of the transmission line corridors would be reallocated to non-timber production use. This change would ensure that the proposed use of the area matches the actual use of the area. Reclaimed plant communities would eventually re-establish diverse plant communities but the overall vegetation diversity would be less than the original plant communities and introduced species would increase. Compliance with the INFS and RHCA standards and guidelines is discussed in section 3.6, *Aquatic Life and Fisheries*. Compliance with standards for old growth is discussed in section 3.22.2, *Old Growth Ecosystems*.

3.22.1.4.14 Irreversible and Irretrievable Commitments

All of the mine alternative and transmission line alternatives would disturb native species-dominated vegetation communities, most of which would be subsequently mitigated by revegetation. Revegetated areas would eventually return to pre-disturbance productivity, but vegetation diversity would be lower than existing conditions. Decreased production of timber during mine and transmission line operations and for several decades after reclamation would be an irretrievable commitment of resources. The tailings impoundment areas, which would disturb about 600 acres in each mine alternative, would be managed for mineral development following operations, and would no longer be managed for timber production. The area covered by asphalt and gravel by widening the Bear Creek Road would not be returned to pre-mine uses. These effects would be an irretrievable commitment of resources. The loss of native plant species and increase in introduced species in all mine and transmission line alternatives would be an irreversible resource commitment.

3.22.1.4.15 Short-term Uses and Long-term Productivity

Mining operations and transmission line construction, operations, and decommissioning for all action alternatives would result in long-term impacts on vegetation communities and productivity. Productivity for forested areas would remain low following reclamation until new timber stands are established. A long-term loss of vegetation diversity from loss of native species would occur for each of the mine alternatives. Introduced species cover and production would increase on the disturbed areas.

3.22.1.4.16 Unavoidable Adverse Environmental Effects

An unavoidable loss of native species and species composition would occur during mining operations. Reclamation of disturbed areas following mining would revegetate most areas to pre-mining forested vegetation production over the long term; vegetation communities would be altered and not all native species would re-establish. Introduced species would increase. This loss of some native species and increase in introduced species would be unavoidable impacts of development.

3.22.2 Old Growth Ecosystems

This section describes vegetative characteristics of old growth forests and features particularly important to wildlife. Old growth habitat is recognized for its unique ecological characteristics that serve as important habitat for both wildlife and some species of rare plants on the KNF. According to the KFP, 58 wildlife species use habitat in old growth forest for breeding and/or feeding. While these species may not solely depend on old growth forests, they require old growth structure for part of their life cycle. Five species (barred owl, great gray owl, pileated woodpecker, boreal red-backed vole, and brown creeper) have a strong preference or possible dependence on old growth.

The KFP identified the pileated woodpecker as the management indicator species for old growth forest habitat and all associated wildlife species (KFP, Appendix 12). Effects on old growth-associated wildlife species are discussed in the pileated woodpecker analysis in section 0, *Pileated Woodpecker*. Forest Service sensitive species and state species of concern associated with old growth (flammulated owl, fisher, and northern goshawk) are also discussed in section 3.25.7, *Other Species of Interest*.

3.22.2.1 Regulatory Framework

The KFP establishes forest-wide goals, objectives, standards, guidelines, and monitoring requirements for old growth. According to KFP guidelines, "old growth should be recognized as an important habitat and managed to ensure its availability and utility to wildlife over time" (USDA Forest Service 1987a). The following standards for old growth forests are listed in the KFP:

- To maintain a minimum of 10 percent of the KNF land base below 5,500 feet in elevation in old-growth timber condition
- To maintain an even distribution of old growth habitat through most major drainages, representing the major forest types in each drainage

KNF Supplement No. 85 to FSM 2432.22 direction is to ensure that a minimum of 10 percent old growth is designated for each 3^{rd}-order drainage or compartment (or a combination thereof) before approving timber harvest (USDA Forest Service 1991).

A goal outlined in the KFP is to "Maintain diverse age classes…including old growth timber in sufficient quality and quantity to maintain viable populations of old growth dependent species and to maintain habitat diversity representative of existing conditions" (USDA Forest Service 1987a). KFP direction specifies that old growth designated as MA 13 will "be managed to retain their old growth characteristics." MA designations, goals, and standards are described in detail in section 3.15.3.2.2, *Management Area Goals and Standards*. Additional direction provided by Castaneda (2004) specifies that "harvest treatments in Forest Plan designated old growth stands (MA 13) will require a Forest Plan amendment."

The MFSA directs the DEQ to approve a facility if, in conjunction with other findings, the DEQ finds and determines that the facility would minimize adverse environmental impact, considering the state of available technology and the nature and economics of the various alternatives. The MMRA does not specifically address effects on old growth habitat. The MMRA requires that lands affected by mining meet the post-mine land uses. The DEQ evaluates in its environmental documents whether the revegetation plans for mine facilities would adequately meet the post-mine land uses.

3.22.2.2 Analysis Area and Methods

The analysis area for evaluating direct, indirect and cumulative impacts of the project on old growth in the KNF includes the Crazy and Silverfish PSUs, which are planning areas generally based on watersheds that encompass project facilities for all alternatives (Figure 86). The analysis area for evaluating direct and indirect impacts of the transmission line on old growth on private and State land consists of all lands that would be disturbed by any of the alternative transmission line alignments, substation or loop line (Figure 86).

Impacts of the mine alternatives on old growth were based on the area that would be disturbed by the mine features and associated roads. Transmission line impacts were based on the clearing width and new and improved roads associated with each alternative. Actual acreage cleared would be less and would depend on tree height, slope, and line clearance above the ground.

Management and characteristics of old growth are discussed and summarized in the following documents that are incorporated by reference: the KFP (Appendix 17, KFP II-1, 7, 22, KFP III-54), Green *et al.* (1992, errata corrected through 2011), Pfister *et al.* (2000), Kootenai Supplement No. 85 to FSM 2432.22 (USDA Forest Service 1991), and Castaneda (2004. The KFP provides a description of old growth by habitat group (warm-dry, cool-moist, warm-moist). Since the release of the KFP, new information on old growth has become available. Pfister *et al.* (2000) conducted a peer review of documents that provide old-growth descriptions and attributes, and concluded that Green *et al.* (1992, errata corrected through 2011) provides the best available source for identifying old growth. As a result, the KNF currently uses Green *et al.* (1992, errata corrected through 2011) as the primary tool for identifying potential old growth stands.

Old growth stands on National Forest System lands were identified based on data from Ranger District files and surveys and the KNF old growth GIS layer. As specified in the KNF Supplement No. 85 to FSM 2432.22, old growth stands were field-verified for the Crazy and Silverfish PSUs. Changes in old growth mapping resulting from recent field verification were incorporated into effects analysis for this Final EIS. Field verification of old growth stands was completed using both walk-through and common stand exam methods, as described in the Vegetation Update Report (Westech 2005d). Stands above 5,500 feet are not suitable for reproduction of most old growth associated wildlife species (USDA Forest Service 1987a) and are not included as part of the old growth MAs or calculations of old growth on the KNF (Figure 86).

Impacts of the alternatives on old growth on National Forest System lands were evaluated according to the following criteria:

- Acres of vertical structure removed in designated old growth. This is the area cleared of designated old growth, including both designated effective and designated replacement old growth
- Acres of vertical structure removed in undesignated effective old growth
- Road length built adjacent to or through designated old growth (in feet)
- Acres affected by edge in old growth
- Acres of interior habitat remaining in old growth
- Acres of old growth designated
- Percent of designated old growth remaining in the PSU

Effective old growth stands support the habitat conditions described in Green *et al.* (1992, errata corrected through 2011). Replacement old growth stands do not meet minimum characteristics to be currently considered old growth, but are expected to become old growth in time. Designated old growth consists of stands that have been allocated to MA 13 in the KFP. Effective old growth stands may have been identified after the KFP was published, and some have not been assigned to MA 13.

Research has indicated that certain activities, in particular regeneration harvest, within or adjacent to old growth stands may influence vegetative characteristics and wildlife use of those stands (Harris 1984; Ripple *et al.* 1991; Morrison *et al.* 1992; Province of British Columbia 1995; Russell *et al.* 2000; Russell and Jones 2001). Although the width of old growth shown to be influenced by edge varies depending on the study (Chen *et al.* 1995), research supports a three-tree height rule of thumb as the distance to which effects occur (Harris 1984; Ripple *et al.* 1991; Morrison *et al.* 1992; Province of British Columbia 1995; Russell *et al.* 2000). On the KNF, the average old growth tree height is 100 feet, based on data from the KNF Timber Stand Management Record System (TSMRS) database. Existing edge effects were estimated by applying a 300-foot buffer to harvested forest habitat (activity codes 4111-4117, 4131, 4132, 4175-4177, 4193, and 4194 or old TSMRS activity codes 4100-4134) less than 30 years old and bordering old growth stands. Effects of alternatives were estimated by applying the same buffer to any resulting old growth edge. Old growth areas 50 acres in size and greater not affected by edge effects provide interior habitat.

Old growth mapping for private and State lands along the transmission line was based on photo-interpretation of 2006 aerial imagery and field verification conducted by a Forest Service biologist in 2008. Private land in the Little Cherry Creek impoundment disturbance area has been mostly harvested and was not surveyed for old growth. Impacts on old growth on private lands were evaluated based on the extent of mapped old growth affected.

3.22.2.3 Affected Environment

Old growth forest consists of mature and over-mature stands that provide habitat for many wildlife species. The KFP Appendix 17, A17-2, classifies old growth as a "distinct successional stage" having specific characteristics. It defines the "classic" old growth stand as one that is physically imposing with tall, full-crowned trees; large standing dead material; fallen dead material; a dense canopy; and having moderated temperatures. According to Green *et al.* (1992, errata corrected through 2011) old growth "…encompasses the later stages of stand development that typically differ from earlier stages in characteristics such as tree age, tree size, number of large trees per acre, and basal area. In addition, attributes such as decadence, dead trees, the number of canopy layers, and canopy gaps are important but more difficult to describe because of high variability."

3.22.2.3.1 Existing Old Growth Stands on the KNF

Existing conditions of old growth forest in the KNF portion of the analysis area are a result of past disturbance processes, primarily historical timber harvest and wildfires (USDA Forest Service 2003b). Old growth stands occupying mesic sites in the analysis area are dominated by western hemlock and western redcedar. Common subdominant conifers at these sites include grand fir, Engelmann spruce, Douglas-fir, and western larch. While western white pine is present at these sites, the majority occur as dead snags, having succumbed to whitepine blister rust disease. Lower elevation old growth stands are mainly composed of Douglas-fir, ponderosa pine, western larch, grand fir, or lodgepole pine. Mid to upper elevation old growth sites support subalpine fir, western hemlock, western redcedar, grand fir, and Engelmann spruce (Westech 2005d). Old growth forests in the Crazy and Silverfish PSUs are shown on Figure 86.

Old growth management area designations in the PSU were made to conserve the best old growth attributes available and to provide the best distribution, size, habitat type coverage, and quality possible. These old growth stands are physically connected to other old growth stands where possible, or are interconnected to adjacent old growth stands by stands composed of age classes more than 100 years old.

The Crazy PSU contains 55,925 total acres below 5,500 feet, including 47,982 acres of National Forest System lands, 6,702 acres of private lands, and 1,241 acres of State lands. Mature coniferous forest Old growth stands on private and State lands have been mostly harvested. The 8,815 acres of old growth (all categories) remaining on National Forest System lands below 5,500 feet is about 16 percent of all lands, and 18 percent of National Forest System lands below 5,500 feet in the Crazy PSU (Table 177).

The Silverfish PSU contains 60,839 total acres below 5,500 feet, including 52,078 acres of National Forest System lands, 8,146 acres of private lands, and 615 acres of State lands. Mature coniferous forest growth stands on private and State lands have been mostly harvested, and the 6,789 acres of old growth (all categories) remaining on National Forest System lands below 5,500 feet is about 11 percent of all lands, and 13 percent of National Forest System lands below 5,500 feet in the Silverfish PSU.

Currently, total designated effective old growth and replacement old growth occupies 17.3 and 13.6 percent of National Forest System lands below 5,500 feet in the Crazy and Silverfish PSUs, respectively (Table 177). Old growth in both PSUs currently meets KNF standards for maintaining at least 10 percent of the land base in old growth (per FSM 2432.22).

Attributes of Old Growth within the Landscape

As elements of dynamic landscapes, other attributes of old growth stands such as the size of old growth blocks, their juxtaposition and connectivity with other old growth stands, their topographic position, their shapes, their edge, and their stand structure compared to neighboring stands are important to evaluate. To maintain healthy and diverse ecosystems, the full range of natural variation should be represented and landscape mosaics should be managed as a whole (Green *et al.* 1992, errata corrected through 2011). Management activities, such as timber harvest, road construction, or mining, have the potential to impact the function of old growth habitat or specific components of old growth, such as quantity of interior habitat, habitat patch sizes, and vertical structure.

Larger blocks (more than 50 acres) of old growth forest provide interior habitat and connectivity within National Forest System lands. Based on recommendations in Morrison *et al.* (1992), stands smaller than 50 acres were designated to protect additional attributes unique to old growth. Smaller patches of older, forested vegetation may be important stepping stones for dispersal of old growth-dependent wildlife species, especially in heavily fragmented landscapes. Although these patches may not meet criteria for interior conditions, their removal could prevent dispersal of some species across a larger landscape (Morrison *et al.* 1992). In the KNF, small patches of old growth habitat are largely surrounded by multi-aged stands, which also provide corridor links to larger blocks of old growth. Old growth block sizes in the Crazy and Silverfish PSUs are shown in Table 178.

Table 177. Old Growth Status in the KNF and the Crazy and Silverfish PSUs.

Old Growth Status	Crazy PSU Acres[1] (Percent[2])	Silverfish PSU Acres[1] (Percent[2])	KNF Acres[3] (Percent[2])
Total National Forest System lands	60,215	60,515	2,200,000
Total National Forest System lands below 5,500 feet elevation	47,982	52,078	1,869,222
KFP minimum standard for old growth	4,798 (10.0)	5,208 (10.0)	186,922 (10.0)
Designated old growth[4]			
Designated effective[5] old growth	7,862 (16.4)	5,251 (10.1)	139,082 (7.4)
Designated replacement[6] old growth	418 (0.9)	1,433 (2.8)	64,776 (3.4)
Designated unknown[7] (KFP)	0 (0)	0 (0)	20,238 (1.1)
Total designated effective old growth and replacement old growth[8]	8,280 (17.3)	7,102 (13.6)	227,026 (12.1)
Undesignated effective old growth and replacement old growth			
Undesignated effective old growth	488 (1.0)	47 (0.1)	51,111 (2.7)
Undesignated replacement old growth	47 (0.1)	58 (0.1)	32,941 (1.8)
Totals for both designated and undesignated old growth and replacement old growth			
Total designated and undesignated effective old growth[5]	8,350 (17.4)	5,298 (10.2)	201,577 (10.8)
Total designated and undesignated replacement old growth	465 (1.0)	1,491 (2.9)	97,717 (5.2)
All old growth below 5,500 feet (effective and replacement old growth	**8,815 (18.4)**	**6,789 (13.0)**	**299,294 (16.0)**

[1] Updated in 2010. Replacement old growth stands were designated to provide old growth in the future within the PSU.
[2] Percentage calculated based on total National Forest System lands below 5,500 feet elevation.
[3] Forest-wide acres as of July 2012.
[4] Designated old growth: old growth forest designated as an old growth MA, such as MA 13.
[5] Effective old growth: meets all the age and size class old growth requirements, contains typical old growth habitat components, and is large enough or of appropriate shape to allow species dependent on forest interiors to flourish. Effective old growth includes acres inventoried on the ground plus 60 percent of old growth determined by photo interpretation, plus 60 percent of designated unknown old growth, based on results of old growth surveys described in the KFP.
[6] Replacement old growth: stands that do not have enough old growth characteristics to be considered old growth, but that are expected to become old growth in time.
[7] Designation unknown: old growth designated as MA 13 in the KFP that has not been surveyed.
[8] Based on 100 percent of all categories of designated old growth, old growth determined by photo interpretation, and designated unknown old growth rather than 60 percent of these categories. Thus, total designated and replacement old growth is not directly additive.

All old growth in the Crazy PSU, including undesignated and designated effective and replacement old growth, comprises a total of 55 blocks ranging from 10 acres to 2,501 acres. About 55 percent of these blocks are greater than 50 acres. Although there is less old growth in the Silverfish PSU, it contains proportionately more old growth blocks over 50 acres than the Crazy PSU. All old growth in the Silverfish PSU consists of 74 blocks ranging from 1 acre to 513 acres, with about 64 percent of the old growth blocks greater than 50 acres.

Table 178. Old Growth Block Sizes in the Crazy and Silverfish PSUs.

Old Growth Status	Number of Blocks	Size Range (acres)	Number of Blocks Over 50 Acres	Percent Blocks Over 50 Acres
Crazy PSU				
Designated				
Effective	37	10 - 2,501	25	68
Replacement	11	15 - 98	2	18

Stand Structure

Old growth stand structure is described by Green *et al.* (1992, errata corrected through 2011). In summary, Green identifies three structural stages that are useful in describing old growth: late seral single-story (*e.g.*, ponderosa pine, Douglas-fir, or lodgepole pine sites); late seral multi-story (*e.g.*, larch or western white pine sites); and near-climax (*e.g.*, cedar, grand fir, or subalpine fir sites). Old growth stands in the Crazy and Silverfish PSUs can be characterized as predominately multi-story or near-climax (Westech 2005d).

Disturbance

Many roads and trails in the Crazy and Silverfish PSUs either bisect or are adjacent to old growth stands. Roads facilitate pedestrian and motorized access to old growth forest habitats, resulting in increased disturbance to vegetation and wildlife. Roads also increase access for firewood cutters who may remove standing snags and down logs that are important components of old growth forests. Within existing designated old growth in the Crazy and Silverfish PSUs, 41 miles of local roads comprise 13 miles of seasonally restricted roads, 6 miles of roads closed year-round, and 22 miles of roads open year-round. Timber harvesting can affect adjacent old growth stands by altering six microclimatic factors: solar radiation, soil temperature, soil moisture, air temperature, relative humidity, and wind speed (Chen *et al.* 1995). Microclimatic changes lead to vegetation changes such as species richness, diversity, composition, and structure (Russell and Jones 2001).

Changes in vegetative conditions may, in turn, affect wildlife, resulting in changes in associated wildlife communities and influencing other factors such as predation and competition (Askins 2000) (see pileated woodpecker discussed in section 3.25.3, *Management Indicator Species*). Effects of timber harvesting extend varying distances into the uncut stands depending on a number of variables, such as aspect, slope, elevation, wind speed, and direction. The depth of influence is also related to time since harvest, with effects dissipating within 20 to 50 years, depending on the factor (Russell and Jones 2001; Ripple *et al.* 1991; Russell *et al.* 2000). In the Crazy and Silverfish PSUs, average tree growth in stands where regeneration has occurred result in tree heights (20 to 50 feet) and densities (fully stocked stands) that reduce the depth of influence from edge effects after 30 years. Table 180 shows the amount of old growth currently influenced by edge effects, including the number of existing harvested stands (stands less than 30 years old) adjacent to old growth stands. These stands create an edge influence on about 1,744 acres of old growth in the Crazy PSU and about 551 acres of old growth in the Silverfish PSU. While edge areas may result in changes in vegetation and wildlife use, the edge areas remain functional as old growth for some species. Old growth areas not impacted by edge effects provide interior habitat.

3.22.2.3.2 Existing Old Growth Stands on Private and State Lands

The majority of private or state-owned land within the analysis area has been harvested in the past 20 to 30 years (Figure 85) and is heavily roaded. Although most previously harvested areas have well-established conifer regeneration, as described in section 3.22.1, *Vegetation Communities*, these areas do not provide effective old growth habitat. Coniferous forest on private lands is primarily dominated by dry, ponderosa pine/Douglas-fir communities that do not have old growth characteristics. Old growth on private and State lands within the analysis area consists primarily of riparian old growth and occurs mainly in the Fisher River, West Fisher Creek, and Hunter Creek riparian corridors (Figure 86). No old growth stands were identified at the Sedlak Park Substation Site.

3.22.2.4 Environmental Consequences

The following section discusses the direct, indirect, and cumulative effects on old growth for each of the mine alternatives, transmission line alternatives, and combined mine-transmission line alternatives. The mine alternatives would have no effect on old growth in the Silverfish PSU. Impacts on old growth in the Crazy PSU from the mine alternatives are summarized in Table 179. Impacts on old growth in the Crazy and Silverfish PSUs from the transmission line alternatives are summarized in Table 180 and Table 181.

3.22.2.4.1 Alternative 1–- No Mine

Alternative 1 would have no direct effect on designated old growth or associated plant and wildlife species (also see pileated woodpecker discussed in section 3.25.3, *Management Indicator Species*). As shown in Table 179, the conditions for all seven measurement criteria would remain unchanged. All old growth areas would maintain their existing conditions and continue to provide habitat for those species that use the area over a long term. The most recent forest-wide old growth analysis concludes that at least 10 percent of the KNF below 5,500 feet elevation is designated for old growth management (USDA Forest Service 2007d). This alternative would not affect the current proportion of old growth (Table 179) at either the PSU or KNF scale.

Table 179. Summary of Impacts on Old Growth from the Mine Alternatives in the Crazy PSU.

Measurement Criteria	[1] No Mine/ Existing Conditions[1]	[2] MMC's Proposed Mine	[3] Agency Mitigated Poorman Impoundment Alternative	[4] Agency Mitigated Little Cherry Creek Impoundment Area

(#) Change from existing conditions due to the alternative. NA= Not applicable; OG = old growth; ROG = Replacement Old Growth.
[1]Existing conditions for old growth may differ from that presented in the Draft EIS due to changes in old growth mapping resulting from recent field verification.
[2] Includes effective and replacement old growth.
[3] Effective old growth only.
[4] Mitigation for physical loss of old growth would be at a 2:1 ratio.
[5]Mitigation for increased edge effects would be at a 1:1 ratio. Designated old growth (MA 13) within the 500-foot-wide transmission line corridor reallocated as MA 23 would be within the area accounted for by edge effects.
[6]Alternative D-R would result in the removal of an old growth stand that previously contributed to edge, resulting in less edge influence.
Source: GIS analysis by ERO Resources Corp. using KNF data.

3.22.2.4.2 Alternative 2 – MMC's Proposed Mine

Alternative 2 would have the greatest effect on old growth of the mine alternatives, affecting 185 acres of designated old growth and 182 acres of undesignated old growth for a total of 367 acres of old growth habitat affected in the Crazy PSU (Table 179). Old growth in the Silverfish PSU and in private or State land outside the Silverfish PSU would not be affected. Alternative 2 would result in edge effects on about 221 acres of old growth habitat and a loss of about 635 acres of interior old growth habitat. The majority of impacts on designated old growth would occur in the LAD Area 2 at the mouth of Ramsey and Poorman creeks. Trees would be selectively thinned in 200 acres of the LAD Areas where spray irrigation would occur. Although these irrigated areas would likely continue to provide suitable habitat for some old growth-associated species, old growth habitat connectivity could be reduced between the Ramsey Creek and Poorman Creek drainages for other species. All of the impacts on undesignated effective old growth would occur as a result of the Little Cherry Creek Impoundment construction, eliminating 133 acres of a 193-acre old growth block. Reducing the size of old growth blocks would diminish their capacity to support old growth-dependent plant and wildlife species. At the PSU scale, Alternative 2 would result in a 0.4 percent loss of designated old growth in the Crazy PSU. The percent of designated old growth in the Crazy and Silverfish PSUs would remain above the 10 percent minimum standard specified in the KFP.

Alternative 2 would include the construction of about 400 feet of new roads through designated old growth habitat. As a result, less than 1 acre of old growth habitat would be lost. These impacts are included in the impacts on designated and undesignated old growth shown in Table 179. Because new roads would not be open to the public and would be reclaimed at mine closure, they are not likely to reduce snag levels from firewood gathering. Use of new roads associated with mine activities would result in long-term increases in disturbance to vegetation and wildlife.

3.22.2.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Alternative 3 would affect 228 acres of designated old growth and 8 acres of undesignated old growth, for a total of 236 acres of old growth habitat in the Crazy PSU. Old growth in the Silverfish PSU and in private or State land outside the Silverfish PSU would not be affected. Relative to other alternatives, Alternative 3 would result in the most edge effects (277 acres) to old growth habitat. Alternative 3 would result in a loss of about 532 acres of interior old growth habitat (Table 179). The majority of impacts on designated old growth would occur as a result of impoundment construction, reducing old growth habitat connectivity in the Poorman Creek drainage. Reducing the size of old growth blocks would diminish their capacity to support old growth-dependent plant and wildlife species. At the PSU scale, Alternative 3 would result in a 0.5 percent loss of designated old growth in the Crazy PSU, before mitigation was implemented. The percent of designated old growth in the Crazy and Silverfish PSUs would remain above the 10 percent minimum standard specified in the KFP. Alternative 3 would include the construction of about 1,231 feet of new roads through designated old growth habitat. As a result, about 3 acres of old growth habitat would be lost. Other impacts of new roads constructed for Alternative 3 would be the same as Alternative 2. Alternative 3 would involve the reallocation of 48 acres of designated old growth (MA 13) to MA 31 (Mineral Development) that have not been accounted for in direct disturbance and indirect edge effects (Table 179). The reallocation of MAs is described in section 3.15*, Land Use*. Although the MA change would not result in disturbance to or physical loss of old growth, the change would reduce the percent of designated old growth in the PSU. The designation of 797 acres of additional old growth would mitigate this reduction (Table 179).

Alternative 3 would include mitigation described in section 2.5.7.4.4, *Key Habitats* for impacts on old growth, such as the designation of additional old growth shown in Table 179 on National Forest System lands. Designation of additional areas of old growth would not create new old growth, but would ensure that these areas are managed to retain or develop old growth characteristics. Alternative 3 mitigation would increase the percent of designated old growth in the Crazy PSU to 18.3 percent. Losses and degradation of old growth habitat may be offset by private land acquisition associated with grizzly bear habitat mitigation, if old growth habitat characteristics were present on the acquired parcels.

3.22.2.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Alternative 4 would have the least effect on old growth habitat of the mine alternatives, affecting 82 acres of designated old growth and 132 acres of undesignated old growth, for a total of 214 acres of old growth habitat in the Crazy PSU. Old growth in the Silverfish PSU and in private or State land outside the Silverfish PSU would not be affected. At the PSU scale, Alternative 4 would result in a 0.2 percent loss of designated old growth in the Crazy PSU. Impacts of new roads constructed for Alternative 4 would be the same as those described for Alternative 3.

Alternative 4 would result in edge effects on about 214 acres of old growth habitat. Relative to the other mine alternatives, the least amount of interior old growth habitat (491 acres) would be lost as a result of Alternative 4.

Alternative 4 would involve the reallocation of 199 acres of designated old growth (MA 13) to MA 31 (Mineral Development) that have not been accounted for in direct disturbance and indirect edge effects. Although the MA change would not result in disturbance to or physical loss of old growth, the change would reduce the percent of designated old growth in the PSU. The designation of 828 acres (Table 179) of additional old growth would mitigate this reduction.

Mitigation for impacts on old growth for Alternative 4 would be similar to Alternative 3, except that Alternative 4 mitigation would increase the percent of designated old growth in the Crazy PSU to 181.1 percent.

3.22.2.4.5 Alternative A – No Transmission Line

Alternative A would have no direct effect on designated old growth or associated plant and wildlife species (also see discussion in section 0, *Key Habitats*). The conditions for all seven measurement criteria (Table 180; Table 181) would remain unchanged. All old growth areas would maintain their existing conditions, and continue to provide habitat for those species that use the area over a long term. The most recent forest-wide old growth analysis concludes that at least 10 percent of the KNF below 5,500 feet elevation is designated for old growth management. This alternative would not affect the current proportion of old growth (Table 180; Table 181) at either the PSU or KNF scale.

3.22.2.4.6 Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

Alternative B would have the greatest impact on old growth habitat of the transmission line alternatives, affecting 20 acres of designated old growth in the Crazy PSU (Table 180). Seven acres of undesignated old growth would be affected by Alternative B. Two acres of undesignated old growth would be affected by Alternative B in the Silverfish PSU. Designated old growth in the Silverfish PSU would not be affected by Alternative B (Table 181). Alternative B would result in edge effects on about 98 acres of old growth habitat and a loss of about 125 acres of interior old growth habitat in the Crazy PSU. In the Silverfish PSU, edge effects would occur on 23 acres, and 28 acres of interior habitat would be lost. Alternative B would remove about 4 acres of old growth habitat on private land along the Fisher River and a short portion of Miller Creek. The substation and loop line would not affect old growth habitat. Loss of old growth habitat and edge effect may be offset by private land acquisition associated with grizzly bear habitat mitigation, if old growth habitat characteristics were present on the acquired parcels.

The majority of impacts on old growth would occur in the Ramsey Creek corridor and at the confluence of Libby and Howard creeks, reducing old growth habitat connectivity in these drainages. Reducing the size of old growth blocks would diminish their capacity to support old growth-dependent plant and wildlife species. At the PSU scale, the loss of old growth would have negligible effects on the proportion of old growth in the Crazy PSU (Table 180). The percent of designated old growth in the Crazy and Silverfish PSUs would remain above the 10 percent minimum standard specified in the KFP.

Alternative B would include the construction of about 2,851 feet of new roads through designated old growth habitat, affecting less than 3 acres of old growth habitat (Table 180; Table 181). Because new roads would not be open to the public, would undergo interim reclamation after construction, and would be bladed and recontoured to match existing topography at transmission line decommissioning, the roads are not likely to reduce the amount of snag levels from firewood gathering. Use of new roads associated with transmission line construction would result in short-term disturbance to vegetation and wildlife.

3.22.2.4.7 Alternative C-R – Modified North Miller Creek Transmission Line Alternative

For Alternative C-R, no designated old growth habitat would be removed in the Crazy PSU, and 4 acres would be removed in the Silverfish PSU (Table 180; Table 181). No undesignated old growth would be removed by Alternative C-R in the Crazy PSU, while 2 acres of undesignated old growth in the Silverfish PSU would be affected. Alternative C-R would result in 17 acres of edge effects on old growth habitat in the Silverfish PSU, but would not change edge effects in the Crazy PSU Alternative C-R would result in a loss of about 39 acres of interior old growth habitat in the Silverfish PSU, but would not affect interior old growth in the Crazy PSU. Alternative C-R would not affect old growth habitat on private land (Figure 86).

The majority of impacts on old growth would occur on the ridge between Miller and West Fisher creeks and upslope of the unnamed tributary to Miller Creek. Reducing the size of old growth blocks would diminish their capacity to support old growth-dependent plant and wildlife species. At the PSU scale, the loss of old growth would have a negligible effect on the proportion of old growth composition and would not measurably impact old growth characteristics and attributes in the Crazy or Silverfish PSU or the KNF. The percent of designated old growth in the Crazy and Silverfish PSUs would remain above the 10 percent minimum standard specified in the KFP. Alternative C-R would include the construction of 116 feet of new roads through designated old growth habitat in the Silverfish PSU and none in the Crazy PSU.

Mitigation for impacts of Alternative C-R on National Forest System lands would include the designation of additional old growth shown in Table 180 and Table 181. Alternative C-R mitigation would maintain the percent of designated old growth in the Crazy PSU at 17.3 percent and increase it in the Silverfish PSU to 13.7 percent. Loss of old growth habitat and edge effect may be offset by private land acquisition associated with grizzly bear habitat mitigation, if old growth habitat characteristics were present on the acquired parcels.

3.22.2.4.8 Alternative D-R – Miller Creek Transmission Line Alternative

Effects on old growth from Alternative D-R in the Crazy PSU would be the same as Alternative C-R, except that it would result in 4 acres of edge effects on old growth habitat and would affect 4 acres of interior habitat (Table 181). Alternative D-R effects would be the same as Alternative C-R in the Silverfish PSU, except that less interior old growth habitat would be affected and edge effects would decrease by four acres due to removal of an old growth stand that previously contributed to edge.

Mitigation for impacts of Alternative D-R on National Forest System lands would include the designation of additional old growth shown in Table 180; Table 181. Alternative D-R mitigation would maintain the percent of designated old growth in the Crazy PSU at 17.3 percent and in the Silverfish PSU at 13.6 percent. The loss of old growth habitat and edge effects may be offset by private land acquisition associated with grizzly bear habitat mitigation, if old growth habitat characteristics were present on the acquired parcels.

3.22.2.4.9 Alternative E-R – West Fisher Creek Transmission Line Alternative

Effects on old growth from Alternative E-R in the Crazy PSU would be the same as Alternative D-R. In the Silverfish PSU, old growth habitat would not be affected by Alternative E-R, except for 2 acres of increased edge effects and the loss of 2 acres of interior old growth habitat (Table 180; Table 181). Alternative E-R would directly impact about 7 acres of old growth habitat on private and State land where the transmission line would cross the Fisher River and parallel West Fisher Creek (Figure 86). Impacts on old growth on non-National Forest System lands would be minimized through implementation of the Environmental Specifications (Appendix D) and Vegetation Removal and Disposition Plan. Also, the use of monopoles in old growth habitat, if incorporated into the Vegetation Removal and Disposition Plan, would require less clearing.

3.22.2.4.10 Combined Mine-Transmission Line Effects

Direct impacts of the mine alternatives in combination with the transmission line alternatives are shown in Table 182. Impacts on old growth from combined mine and transmission line alternatives before mitigation would be the greatest (395 acres of old growth removed in the Crazy and Silverfish PSUs) for MMC's proposed alternative (Alternative 2B). Old growth removed in the Crazy and Silverfish PSUs for the agencies' alternatives (Alternatives 3C-R, 3D-R, 3E-R, 4C-R, 4D-R, and 4E-R), including private and State land, would range from 214 acres for Alternative 4E-R to 242 acres for Alternatives 3C-R. The agencies' alternatives would include mitigation for impacts on old growth, such as the designation of additional old growth on National Forest System lands shown in Table 182 and implementation of the Environmental Specifications and Vegetation Removal and Disposition Plan. Designation of additional areas of old growth would not create new old growth, but would ensure that these areas are managed to retain or develop old growth characteristics. With mitigation, the agencies' combined alternatives would result in an increased proportion of designated old growth on National Forest System lands. For the agencies' alternatives, impacts on old growth on private land would be minimized through implementation of the Environmental Specifications and Vegetation Removal and Disposition Plan. The use of monopoles in old growth habitat, if incorporated into the Vegetation Removal and Disposition Plan, would require less clearing. For all combined alternatives, losses and degradation of old growth habitat may be offset by private land acquisition associated with grizzly bear habitat mitigation, if old growth habitat characteristics were present on the acquired parcels.

3.22.2.4.11 Effectiveness of agencies' Proposed Mitigation

In the agencies' alternatives, additional old growth on would be designated National Forest System lands to mitigate impacts on old growth. While the designation of additional old growth would not create new old growth, it would ensure that these areas are managed to retain or develop old growth characteristics. Old growth management area designations are made to conserve the best old growth attributes available and to provide the best distribution, size, habitat type coverage, and quality possible. While designated replacement old growth stands do not have enough characteristics to be currently considered old growth, they are expected to become old growth in time. Implementation of Environmental Specifications and Vegetation Removal and Disposition Plan would help reduce clearing of old growth. Designation of old growth would not replace old growth lost, and given the recovery time of old growth forest (200-250 years), mitigation of effects after stand-replacing disturbance would likely require centuries.

3.22.2.4.12 Cumulative Effects

Past actions, particularly timber harvest, road construction, and fire suppression activities, have altered the old growth ecosystems in the analysis area, resulting in reductions in early and late succession habitats; conditions favoring shade-tolerant, fire-intolerant species; loss of large snags and down wood; and increases in tree density and a shift to a largely mid-seral structural stage (USDA Forest Service 2003b). Firewood cutting would continue to occur where open roads provide access to old growth habitat, contributing to snag removal. Continuing development of private lands, including timber harvest, home construction, and land clearing would contribute to losses of old growth habitat in the analysis area, but would not affect the proportion of old growth on National Forest System lands. In addition, it is likely that limited amounts of old growth occur on private and State lands, based on past and current harvest practices. The No Action Alternatives (Alternative 1 and Alternative A) would not contribute to cumulative impacts on old growth.

Regeneration harvest included in the Miller-West Fisher Vegetation Management Project, which will occur in the Silverfish PSU, would not directly affect old growth. The Miller-West Fisher Vegetation Management Project will result in minor increased edge effects where regeneration harvest is proposed adjacent to old growth. Currently, total designated effective old growth and replacement old growth occupies 17.3 and 13.6 percent of National Forest System lands below 5,500 feet in the Crazy and Silverfish PSUs, respectively (Table 177), above the 10 percent minimum standard specified in the KFP. While the action alternatives, in combination with other past, current, and reasonably foreseeable actions, would result in some losses and degradation of old growth habitat, cumulative impacts on levels of old growth would likely be minimal. In addition, mitigation associated with the agencies' Alternatives 3, 4, C-R, D-R, and E-R would increase the proportion of designated old growth and promote the maintenance or development of old growth in the analysis area.

Table 182. Summary of Impacts on Old Growth from Combined Mine and Transmission Line Alternatives.

Old growth removed (acres)	0	4	0	0	7	0	0	7

(#) number in parentheses is the change due to the alternative. OG = Old growth ROG = Replacement Old Growth; N/A = Not Applicable
[1]Existing conditions for old growth may differ from that presented in the Draft EIS due to changes in old growth mapping resulting from recent field verification.
[2]Includes effective and replacement old growth. Acreage may not equal that shown in Table 179 and Table 180 and Table 181 because of overlapping effects.
[3]Effective old growth only.
[4]Mitigation for physical loss of old growth would be at a 2:1 ratio.
[5]Mitigation for increased edge effects or reallocation of designated old growth (MA 13) to MA 31 (Mineral Development) would be at a 1:1 ratio.
[6]Alternative 3-DR and 4D-R would result in the removal of an old growth stand that previously contributed to edge, resulting in less edge influence.
Source: GIS analysis by ERO Resources Corp. using KNF data.

3.22.2.4.13 Regulatory/Forest Plan Consistency

All action alternatives would require a project-specific amendment to allow harvest within designated old growth stands (MA 13). The project-specific amendment would change the current MA 13 (Designated Old Growth) designation of all harvested stands to either MA 23 (Electric Transmission Corridor) or 31 (Mineral Development). All action alternatives would be consistent with KFP direction to maintain a minimum of 10 percent old growth below 5,500 feet in elevation in each 3rd-order drainage or compartment, or a combination of compartments.

Forest-wide analysis of old growth (USDA Forest Service 2007d) indicates that at least 10 percent of the KNF below 5,500 feet is managed as old growth, as required in the KFP. Specifically, National Forest System lands below 5,500 feet include 299,294 acres (16.0 percent) of old growth or replacement old growth (Table 177). About 10.8 percent (201,577 acres) of those lands were determined to be effective old growth, and 5.2 percent (97,717 acres) were identified as replacement old growth.

The action alternatives would result in between 16.4 and 18.3 percent designated old growth below 5,500 feet elevation in the Crazy PSU, and between 13.6 and 13.7 percent designated old growth below 5,500 feet elevation in the Silverfish PSU. The KFP established that maintaining 10 percent of old growth habitat is sufficient to support viable populations of old-growth dependent species (KFP, Vol. 1, II-1, 7, III-54; Vol. 2, A17).

Other applicable standards established in the KFP for MA 13 (Designated Old Growth) include:

Recreation: All action alternatives would comply with these standards. A forest closure order exists to off-highway vehicles, which restricts the off-highway vehicles to established roads and trails.

Wildlife and Fish: All action alternatives would comply with these standards. Activities that potentially conflict with grizzlies in Management Situation 1 and 2 grizzly habitat are described in section 3.25.5.2, *Threatened and Endangered Species.*

Soil, Water, and Air: All alternatives would comply with these standards. As described in sections 3.19, *Soils and Reclamation* and 3.4, *Air Quality*, all action alternatives would comply with soil standards in the KFP and MAAQS. For all action alternatives, BMPs would be implemented to reduce erosion and sedimentation.

Riparian: Compliance with INFS standards are discussed in section 3.6, *Aquatic Life and Fisheries*.

Timber: Firewood cutting could impact snags located in old growth habitat, and this effect is taken into consideration in the cavity habitat analysis in section 3.25.2.2, *Snags and Woody Debris*. Timber harvest would occur, as shown in Table 179 and Table 180 and Table 181. All action alternatives require a project-specific amendment to allow harvest within designated old growth stands (MA 13). The project-specific amendment would change the current MA 13 (Designated Old Growth) designation of all harvested stands to either MA 23 (Electric Transmission Corridor) or 31 (Mineral Development).

Facilities: All action alternatives would comply with these standards. Some areas of MA 13 would be reallocated to MA 31 (Mineral Development) or MA 23 (Electric Transmission

Corridor) for each action alternative. For all action alternatives, some currently closed or restricted roads would be open to mine traffic, but would not be accessible to the public (see Table 13 for Alternative 2, Table 23 for Alternative 3, Table 35 for Alternative 4). All action alternatives would continue to restrict motorized access on other local roads where closures exist.

3.22.2.4.14 Irreversible and Irretrievable Commitments

All action alternatives would result in an irreversible commitment of old growth forest in the Crazy PSU and, except for Alternative E-R, the Silverfish PSU. Transmission line alternatives B and E-R would result in an irreversible commitment of old growth forest in small areas of private land along the transmission line corridor near US 2. Irretrievable commitments of old growth resources in the Silverfish PSU would occur due to indirect impacts from minor edge effects. The recovery time of old growth forest would preclude restoration for centuries following disturbance (200-250 years).

3.22.2.4.15 Short-term Uses and Long-term Productivity

Losses of old growth habitat resulting from implementation of the action alternatives would be long-term, and would be primarily in the Crazy PSU, small areas in the Silverfish PSU, and in small areas of old growth on private land along the transmission line corridor. All alternatives would result in minor edge effects, which would continue beyond the Closure Phase. If reclamation were successful and successional processes were allowed to take place, edge effects would eventually dissipate. Given the recovery time of old growth forest, direct elimination of effects after disturbance would likely require centuries (200-250 years).

3.22.2.4.16 Unavoidable Adverse Environmental Effects

Unavoidable adverse effects would occur from all action alternatives in the Crazy and Silverfish PSUs and small areas of private land along the transmission line corridor where old growth habitat would be directly removed.

3.22.3 Threatened, Endangered, and Sensitive Plant Species

The KNF monitors plant species considered to be of concern. Plant species of concern are characterized as threatened, endangered, sensitive, or Category 4 watch species. T&E species include species listed by the USFWS and protected under the ESA. Forest Service sensitive species are those species the Regional Forester determines to be a concern on National Forest System lands in the Region due to declining numbers. The KNF works closely with the MNHP, which maintains records of plant species of concern. State-listed plant species of concern are also discussed in the following sections.

3.22.3.1 Regulatory Framework

Section 3.6, *Aquatic Life and Fisheries* discusses the regulatory framework for federal-listed threatened or endangered plant species, and Forest sensitive plant species. Two Forest sensitive plant species of concern were found in the analysis area, the northern beechfern (*Phegopteris connectilis)* and crenulated moonwort *(Botrychium crenulatum)*. The KFP requires the maintenance of diverse age classes of vegetation for viable populations of all existing native, vertebrate wildlife species.

There are no regulatory requirements to protect Forest sensitive or state plant species of concern on private land. The DEQ strives to work with proponents of mine development to voluntarily limit impacts on Forest sensitive or state plant species of concern. The MFSA directs the DEQ to approve a facility if, in conjunction with other findings, the DEQ finds and determines that the facility would minimize adverse environmental impacts, considering the state of available technology and the nature and economics of the various alternatives.

3.22.3.2 Analysis Area and Methods

The analysis area consists of all areas that would be disturbed by construction of the mine, transmission line, substation and loop line under any alternative (Figure 85). Potential habitat for sensitive plants was surveyed in areas surrounding facilities as proposed in 1989. Sensitive plant surveys followed KNF guidelines and procedures and were conducted during the summers of 1988 and 1989 (Western Resource Development Corp. 1989d, 1989e), with additional updates in the summer of 2005 (Westech 2005c). During the sensitive plant survey, habitats for sensitive plants were thoroughly examined and the remainder of the analysis area was less thoroughly examined (Westech 2005c). Additional sensitive plant inventories of the Poorman Tailings Impoundment Site, the Libby Plant Site, and the Upper Libby Adit Site were conducted in June and August of 2007 (Geomatrix 2009b). Information from these surveys was used to determine effects on plant species of concern. MNHP records are used in this summary to describe the characteristics of plant species of concern found during surveys of the analysis area. No surveys specifically for Category 4 watch species were conducted in the analysis area. Category 4 watch species were identified and recorded during surveys and are included in vascular plant species lists identified in the analysis area (Westech 2005c) and are not discussed further. Surveys for sensitive plants were not completed for all segments of all transmission line alternatives because a final alignment has not been selected and suitable habitat for sensitive plants could be avoided through design and placement of the transmission line structures. Surveys for sensitive plants were not completed for the segment in Alternatives C-R, D-R, and E-R from the Sedlak Park Substation north to where the alignment crosses Alternative B segments of Alternative C-R where they differ from Alternative B, a segment of Alternative D-R, and the entire alignment of Alternative E-R. The loop line at the Sedlak Park Substation site also was not surveyed. The remaining segments of the alternatives were surveyed for sensitive plants.

The Regional Forester updated the Forest Service sensitive species list for Region 1 in 2011 (USDA Forest Service 2011f). MMC would update surveys for plant species of concern before any ground-disturbing activities in the agencies' mine and transmission line alternatives. The survey results would be submitted to the agencies for approval. If sensitive plants were identified and adverse effects could not be avoided, MMC would develop appropriate mitigation plans for the agencies' approval. The mitigation would be implemented before any ground-disturbing activities. To the extent feasible, MMC would make adjustments to structure and road locations, and other disturbing activities to reduce impacts.

3.22.3.3 Affected Environment

One federal-listed threatened plant species was identified to potentially occur in the analysis area: Spalding's campion (*Silene spaldingii*). Suitable habitat for federal-listed or candidate species was evaluated and determined to be limited in the analysis area (Westech 2005c). No federal-listed T&E plant species were found in the analysis area and T&E plant species are not discussed further.

Two Forest Service sensitive plant species were found in the analysis area: the northern beechfern (*Phegopteris connectilis*) and crenulated moonwort (*Botrychium crenulatum*). Northern beechfern is found at 22 locations in scattered populations in northwestern Montana in Flathead, Glacier, Lincoln, and Sanders counties (MNHP 2014). Three of the occurrences are on the Libby Ranger District of the KNF. Northern beechfern is found in populations ranging from 10 to 100 individuals on benches above Little Cherry Creek in the analysis area (Westech 2005c). Past timber harvesting likely led to declines in the species' abundance and distribution (MNHP 2014). The MNHP classified the northern beechfern as secure globally, but imperiled in Montana because of rarity within the state. Habitat characteristics for the northern beechfern include old growth and mature western redcedar and western hemlock, which occur in the coniferous forest community. Understory plants found with northern beechfern are queencup beadlily, devil's club and lady fern. Management goals for northern beechfern population and genetic viability associated with each are discussed in the KNF Conservation Assessment Report prepared as a result of the 1992 Montanore Project EIS (KNF 1993).

The crenulated moonwort is a small, perennial fern that has been found at several locations in western Montana. Habitat for the crenulated moonwort is mesic areas associated with streams, seeps and western red cedar and western hemlock forests but also includes roadsides and other disturbed areas. During surveys in 2005 for the Montanore Project, two populations were found in riparian areas along Libby Creek and Little Cherry Creek (Westech 2005c). Suitable habitat is present within the Poorman Impoundment Site, but crenulated moonworts were not found during 2007 surveys (Geomatrix 2007d).

Dryland forests along the transmission line corridors have potentially suitable habitat for three Forest sensitive species: taper-tipped onion (*Allium acuminatum*), common clarkia (*Clarkia rhomboidea*), and bank monkeyflower (*Mimulus clivovola*). Limited plant surveys have been done along the transmission line corridor and the presence of these species is unknown.

3.22.3.4 Environmental Consequences

3.22.3.4.1 Alternative 1 – No Mine

The No Mine Alternative would not affect any Forest sensitive or other state-listed plant species of concern.

3.22.3.4.2 Alternative 2 – MMC's Proposed Mine

In Alternative 2, two Forest sensitive and state-listed plant species of concern would be affected, the northern beechfern and the crenulated moonwort. Northern beechfern and the crenulated moonwort populations are located along Little Cherry Creek in the Tailings Impoundment Site (Westech 2005c). A population of northern beechfern and a population of crenulated moonwort would be eliminated in the Little Cherry Creek tailings impoundment site. Northern beechfern is found in 22 other locations across northwestern Montana with (MNHP 2014). The crenulated moonwort has 139 observations at more than 50 locations in Montana. The other populations of both the northern beechfern and the crenulated moonwort are currently secure so viability would not be threatened with the loss of populations in Little Cherry Creek. The KNF's Conservation Assessment (KNF1993) provides additional information on the northern beechfern. An increase in noxious weeds from disturbed ground could reduce habitat for forest sensitive and state-listed plant species of concern.

3.22.3.4.3 Alternative 3 – Agency-Mitigated Poorman Impoundment Alternative

Alternative 3 would not affect any Forest sensitive and state-listed plant species of concern since no sensitive species were identified during field surveys. MMC would update surveys for plant species of concern before any ground-disturbing activities in the agencies' alternatives. If a species of concern was identified and adverse effects could not be avoided, MMC would develop appropriate mitigation plans for the agencies' approval. The mitigation would be implemented before any ground-disturbing activities.

3.22.3.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

The effect on Forest sensitive and state-listed plant species of concern for Alternative 4 would be the same as Alternative 2. MMC would update surveys for plant species of concern before any ground-disturbing activities in the agencies' alternatives. If a species of concern was identified and adverse effects could not be avoided, MMC would develop appropriate mitigation plans for the agencies' approval. The mitigation would be implemented before any ground-disturbing activities.

3.22.3.4.5 Alternative A – No Transmission Line

In Alternative A, the transmission line, substation, and loop line for the Montanore Project would not be built. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

3.22.3.4.6 Alternatives B

All of Alternative B was surveyed for Forest sensitive or other state-listed plant species of concern, and none were identified. Taper-tipped onion, common clarkia, and bank monkeyflower have been added as Forest sensitive species since the previous survey was conducted, and surveys would be updated before construction.

3.22.3.4.7 Alternatives C-R, D-R, and E-R

No Forest sensitive or other state-listed plant species of concern were identified along the transmission line corridors surveyed. Surveys for sensitive plants were not completed for all segments of all transmission line alternatives because a final alignment has not been selected and suitable habitat for sensitive plants could be avoided through design and placement of the transmission line structures. Surveys for sensitive plants were not completed for the segment in Alternatives C-R, D-R, and E-R from the Sedlak Park Substation north to where the alignment crosses Alternative B segments of Alternative C-R where they differ from Alternative B, a segment of Alternative D-R, and the entire alignment of Alternative E-R. The loop line alignment at the Sedlak Park Substation site also was not surveyed. The remaining segments of the alternatives were surveyed for sensitive plants.

MMC would update surveys for plant species of concern, including newly listed species, before any ground-disturbing activities in the agencies' alternatives. If a species of concern was identified and adverse effects could not be avoided, MMC would develop appropriate mitigation plans for the agencies' approval. The mitigation would be implemented before any ground-disturbing activities. To the extent feasible, MMC would make adjustments to structure and road locations, and other ground-disturbing activities to reduce impacts.

3.22.3.4.8 Effectiveness of agencies' Proposed Mitigation

Updating surveys and developing avoidance and mitigation measures would effectively minimize effects on Forest sensitive or other state-listed plant species of concern.

3.22.3.4.9 Cumulative Effects

No other reasonably foreseeable projects in the region, including the Miller-West Fisher Vegetation Management Project, would directly impact federal-listed, Forest sensitive, or state-listed plant species of concern.

3.22.3.4.10 Regulatory/Forest Plan Consistency

The No Action alternatives would not impact any sensitive plant species or their habitat. ***Alternatives 2 and 4 would impact individuals and habitat but would not likely contribute to a trend toward federal listing or cause a loss of viability for Northern beechfern and crenulated moonwort. Alternative 3 may impact individuals or habitat but would not likely contribute to a trend toward federal listing or cause a loss of viability to the population or species. All alternatives transmission line locations may impact individuals of or habitat for taper-tipped onion, common clarkia, and bank monkeyflower but would not likely contribute to a trend toward federal listing or cause a loss of viability to the population or species.***

3.22.3.4.11 Irreversible and Irretrievable Commitments

An irretrievable commitment of resources would occur in Alternatives 2 and 4 from the loss of two populations of Forest sensitive and state-listed plant species of concern. Reclamation of habitat upon completion of mining would not recreate the habitat or necessarily provide conditions suitable for establishment of affected species. Increases in populations of introduced species after disturbance may limit the potential for re-establishment of these species.

3.22.3.4.12 Short-term Uses and Long-term Productivity

Mine operations would result in the long-term loss of one population of northern beechfern and one population of crenulated moonwort in Alternatives 2 and 4.Reclamation of habitat following mining would not recreate the habitat for affected species. Increases in populations of introduced species after disturbance may limit the potential for re-establishment of these species.

3.22.3.4.13 Unavoidable Adverse Environmental Effects

Long-term loss of one population of northern beechfern and one population of crenulated moonwort would occur in Alternatives 2 and 4. It is currently unknown whether any populations of taper-tipped onion, common clarkia, and bank monkeyflower would be lost. Surveys for these species would occur prior to ground-disturbing activities along the selected transmission line corridor. Preconstruction surveys and development of mitigation for unavoidable impacts are discussed in section 2.5.2.5, *Final Design Process.*

3.22.4 Noxious Weeds

3.22.4.1 Regulatory Framework

The term "noxious weed" is defined in the Federal Plant Protection Act and in some individual State statutes. The term "noxious weed" means any plant or plant product that can directly or indirectly injure or cause damage to crops (including nursery stock or plant products), livestock, poultry, or other interests of agriculture, irrigation, navigation, the natural resources of the United States, the public health, or the environment. The term typically describes species of plants that have been determined to be undesirable or injurious in some capacity (USDA Forest Service 2011g). Executive Order 13112 directs federal agencies to prevent the introduction of invasive species; provide for their control; and minimize the economic, ecological, and human health impacts that invasive species cause.

The Montana County Weed Control Act (7-22-2101 *et seq.,* MCA) defines noxious weeds as "any exotic plant species established or that may be introduced in the state which may render land unfit for agriculture, forestry, livestock, wildlife, or other beneficial uses or that may harm native plant communities and that is designated a state noxious weed by rule of the Department of Agriculture; or a noxious weed by a county board." It also states that it is unlawful for any person to permit any noxious weed to propagate or go to seed on his land. The KNF has signed a memorandum with Lincoln County and has agreed to assist and cooperate with the Lincoln County Weed District in managing noxious weeds. The Forest Service's guidelines for controlling noxious weeds are provided in the FSM 2900 Invasive Species Management (USDA Forest Service 2011g), R1 Supplement 2080 Noxious Weed Management 2001, and Appendix A of the KNF Invasive Plant Management Final EIS (KNF 2007a). The Lincoln County Weed District has identified several species of noxious weeds that occur or potentially occur in Lincoln County (Lincoln County 2008). The DEQ requires that mine operations have a weed control plan approved by the local county weed control board.

3.22.4.2 Analysis Area and Methods

The analysis area consists of all areas that would be disturbed by construction of the mine, transmission line, substation and loop line under any alternative (Figure 85).

Noxious weed baseline surveys for the Montanore Project facilities as proposed in 1989 were conducted during the summers of 1988 and 1989 (Western Resource Development Corp. 1989d, 1989e). Noxious weed surveys were updated in 2005 to determine if the weed species or distribution had changed (Westech 2005b). Most proposed mine facility locations and transmission line alternatives were surveyed for noxious weeds. The areas not surveyed for threatened, endangered, or sensitive species also were not surveyed for noxious weeds. Areas not evaluated for noxious weeds are believed to have similar noxious weed infestations and would require similar control methods.

The potential for noxious weed introduction and establishment for the alternatives evaluated was determined based on existing weed populations, total amount of disturbance, and plans to control weeds and revegetate disturbed areas.

3.22.4.3 Affected Environment

Noxious weeds are categorized by the state, county, and Forest Service for management and control. Lincoln County categorizes noxious weeds in Categories I through IIIb (Lincoln County 2008). Lincoln County Category I species are weeds that cover extensive areas, Category II are well established, IIIa are potential invaders, and IIIb are new invaders. Potential invaders include noxious weeds that do not currently exist in Lincoln County but have a high probability of causing severe environmental or economic degradation. (Lincoln County 2008).

The State of Montana identifies Priority 1A, 1B, 2A, 2B, and 3. IA includes weeds not present in Montana, 1B have limited presence, 2A are common in isolated areas of Montana, 2B are abundant in Montana and widespread in many counties and Priority 3 species are regulated plants, but are not listed as Noxious Weeds in Montana. The KNF noxious weed plans (KNF Noxious Weed Handbook, Spring 2008, Edition 5.0) categorize noxious weeds into three categories; Category 1 are well established, Category 2 are new invaders and Category 3 are potential invader species, groupings that are similar to Lincoln County but have different priorities. Noxious weed categories are listed in Table 183.

Table 183. Noxious Weeds Found in the Analysis Area.

Weed Species	Scientific Name†	State Category	Lincoln County Weed Category	KNF Weed Category
Canada thistle	*Cirsium arvense*	2B	II	1
Common tansy	*Tanacetum vulgare*	2B	II	1
Meadow hawkweed	*Hieracium caespitosum*	2A	I	1
Orange hawkweed	*Hieracium aurantiacum*	2A	I	1
Ox-eye daisy	*Leucanthemum vulgare*	2B	I	1
Spotted knapweed	*Centaurea stoebe*	2B	I	1
St. Johnswort	*Hypericum perforatum*	2B	I	1
Sulphur cinquefoil	*Potentilla recta*	2B	I	1
Tall buttercup	*Ranunculus acris*	2A	IIIa	2

†Scientific name from USDA Natural Resources Conservation Service 2008.

Canada thistle is a deep-rooted, creeping perennial that is native to Eurasia. In the analysis area, Canada thistle is common in disturbed swales, mesic areas, and in wetlands where logging has occurred. Monocultures characterized by a high density of Canada thistle are present as scattered plants with low concentrations (Westech 2005b).

KNF Category 1 and 2, State Category 2A and B and 2, and Lincoln County Category I, II, and IIIa species were observed in several locations in the analysis area. Nine species of noxious weeds were found in the analysis area during the 2005 baseline vegetation studies: Canada thistle; spotted knapweed; ox-eye daisy; orange hawkweed; meadow hawkweed; St. Johnswort; sulfur cinquefoil; tall buttercup; and common tansy (Westech 2005b). In addition, Dalmatian toadflax has been found in the Miller Creek drainage, and rush skeletonweed has been found in the Miller Creek and West Fisher Creek drainages. The 1988 vegetation baseline inventory (Western Resource Development Corp. 1989d, 1989e) documented three listed noxious weeds in the analysis area as well as three noxious weeds yet to be officially listed: Canada thistle, spotted knapweed, St. Johnswort, orange hawkweed, ox-eye daisy, and tall buttercup. Meadow hawkweed, sulfur cinquefoil, and common tansy were not recorded in the initial mine analysis area in 1988 but were recorded in 2005.

Common tansy is a perennial forb that is poisonous if ingested. It is not as dominant as the other listed noxious weeds in the analysis area. This species is found most frequently along roads and in disturbed areas, and along riparian corridors. It is common in patches along the Fisher River (Westech 2005b).

Orange hawkweed is a perennial with a fibrous, creeping root system. It has clusters of orange dandelion-like heads and is the most abundant and problematic noxious weed in the Montanore analysis area. It is found mostly in logged and disturbed areas in western hemlock/western redcedar forest types. Most roadsides are dominated by orange hawkweed (Westech 2005b).

Meadow hawkweed has almost identical vegetative growth characteristics to orange hawkweed and is difficult to distinguish without flowering heads. Meadow hawkweed is less common in the analysis area than orange hawkweed, and is found primarily along roads (Westech 2005b).

Once a cultivated species, ox-eye daisy is an invasive weed that is becoming an increasing problem in the western states. Ox-eye daisy is most common along roads and in recently logged areas in the Montanore analysis area (Westech 2005b). It is invading many meadows in northwestern Montana.

Spotted knapweed is an aggressive invader that generally occurs in disturbed areas. Spotted knapweed is a perennial, taprooted Eurasian weed species that invades range and harvested forestland throughout the West. It can reduce biodiversity, wildlife and livestock forage production, and can also increase soil erosion (Montana Noxious Weed Summit Advisory Council 2008). Spotted knapweed grows best in well-drained soils. Spotted knapweed occurs throughout the analysis area, particularly along roads, on disturbed areas, and in areas where timber has been harvested and tree canopy cover is relatively open. Undisturbed areas typically do not have large infestations of spotted knapweed (Westech 2005b).

St. Johnswort is a perennial species that was introduced because of its medicinal properties. Montana’s Department of Agriculture reports that St. Johnswort covers an area of about 68,000 acres in Montana (Montana Noxious Weed Summit Advisory Council 2008). This plant is unpalatable and mildly poisonous to livestock. It is observed along roads and in recent previously harvested coniferous forests but coverage was spotty or minor (Westech 2005b).

Sulfur cinquefoil is a perennial species with well-developed creeping woody roots. Sulfur cinquefoil was recorded in Sedlak Park and along US 2 near the analysis area (Westech 2005b).

Tall buttercup is a perennial species that grows up to 3 feet tall and is poisonous to livestock if ingested. Tall buttercup was present in the 1988 baseline vegetation inventory but was not located during the 2005 baseline vegetation survey (Westech 2005b).

3.22.4.4 Environmental Consequences

3.22.4.4.1 Alternative 1 – No Mine

Introduced species such as cheatgrass and noxious weeds have increased in the analysis area between the time the baseline vegetation surveys were conducted in 1988 and 1989 and the time they were updated in 2005. This increase would continue in the future with or without the mine because of the competitiveness of the introduced species. The No Mine Alternative would not involve new land-disturbing activities and would minimize the increase in number and distribution of introduced species and noxious weeds. Noxious weeds currently present in the analysis area would continue to be subject to existing Forest Service, state, and county-wide noxious weed management practices. Noxious weeds at the Libby Adit Site would continue to be controlled in accordance with existing permits and approvals. Noxious weed control using herbicides can cause an indirect effect on adjacent native species ranging from minimal to severe depending on the type of herbicide and quality of application. Inadequate reseeding efforts to replace native species after treatment cause additional indirect effects on native plant species. The Forest Service and other land managers and owners are not required to control introduced species that are not classified as noxious weeds.

3.22.4.4.2 Alternative 2 – MMC's Proposed Mine

Alternative 2 would increase the spread and establishment of noxious weeds and other introduced species associated with ground-disturbing activities. Weeds invade disturbed ground where they easily establish and out-compete native species even with a weed control program. Weed establishment would more likely occur along roads, cut-and-fill slopes, the margins of mine facilities, soil stockpiles, and other disturbed areas. The distribution of noxious weeds and other introduced species would probably be greatest under Alternative 2 because it includes the largest area of potential disturbance (2,581 acres).

MMC's weed control program would minimize weed infestations on lands disturbed by the proposed facilities. All off-highway vehicles and earth moving equipment entering Lincoln County would be washed at a commercial facility. Special emphasis would be taken to remove soil and other plant material from the vehicle or equipment. MMC would notify KNF at least 24 hours in advance of equipment delivering to the site to provide an opportunity to inspect the equipment. Weed control during operations would primarily be through the use of herbicides. Additionally, a 3-year continuous monitoring and treatment program would be implemented (MMI 2006). Criteria in the reclamation plan for Alternative 2 require that vegetation composition would have less than 10 percent cover of noxious weeds. MMC would not be required to control other introduced species.

3.22.4.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

With 2,011 acres of disturbance, Alternative 3 would have similar potential to increase the infestation and spread of noxious weeds and other introduced species as Alternative 2, although distribution would likely be less. All weed BMPs discussed in section 2.5.3.2.5*, Noxious Weed Mitigation Measures* for Alternative 3 would be implemented, and would reduce the establishment and spread of noxious weeds, compared to Alternative 2. Weed BMPs would address the treatment and control of noxious weeds throughout all mine facilities.

The reclamation plan for reclaimed areas under Alternative 3 differs from Alternative 2 and would require that noxious weeds would have less than 10 percent cover of species listed as Category 1 (established infestations), and 0 percent cover of categories 2 and 3 (potential invaders and new invaders, as described in the KNF Noxious Weed Handbook, Spring 2008, Edition 5.0). Category 1 noxious weeds would not dominate any location greater than 400 square feet. The goal of Alternative 3 would be to use a native seed mix, if commercially available, that would reduce the spread of invasive or noxious species. In Alternative 3, shrubs and trees would be planted by hand in random patterns to prevent the spread or infestation of noxious weeds by limiting disturbance from machinery. MMC would not be required to control other introduced species.

3.22.4.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Alternative 4 would have the same potential to result in the establishment and spread of noxious weeds and other introduced species as described for Alternatives 2 and 3. The reclamation and weed management plans for Alternative 4 would be the same as Alternative 3. MMC would not be required to control other introduced species.

3.22.4.4.5 Alternative A – No Transmission Line

In Alternative A, the transmission line, substation, and loop line for the Montanore Project would not be built. The DEQ's approval of the mine, as permitted by DEQ Operating Permit #00150 and revised in Minor Revisions 06-001 and 06-002, would remain in effect. MMC could continue with the permitted activities on private land associated with the Libby Adit evaluation program that did not affect National Forest System lands. Effects associated with activities at the Libby Adit Site would remain until the site was reclaimed in accordance with existing permits and approvals.

3.22.4.4.6 Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

Alternative B would have the largest area of surface disturbance associated with new or upgraded road construction and timber clearing of the four alternatives (Table 175). New roads would be reseeded as an interim measure, but used for maintenance activities, as necessary. Surface disturbances and continued road use would increase the risk of spread of noxious weed and other introduced species and would require more monitoring and control of noxious weeds. Alternative B would have the least area of vegetation clearing, which would minimize disturbance and potential weed spreading. MMC's weed control program described in Alternative 2 would be implemented for Alternative B, and is designed to minimize weed infestations on lands disturbed by the proposed facilities. Vehicles would be cleaned before entering the area and following work in weed infested areas. BPA's plan to conduct a noxious weed survey at the proposed Sedlak Park Substation Site before and after construction of the substation and its weed control program would minimize noxious weeds at the site. MMC and the BPA would not be required to control other introduced species that are not classified as noxious weeds.

3.22.4.4.7 Effects Common to Transmission Line Alternatives C-R, D-R, and E-R

These alternatives would use a helicopter to construct between 16 and 32 structures, which would minimize new road construction or reconstruction. A helicopter would be used to clear timber in areas adjacent to core grizzly bear habitat. Roads decommissioned or placed in intermittent stored service would not be used for routine maintenance of the transmission line, but could be used for emergency repairs, such as a damaged insulator. These modifications would reduce the risk of noxious weed spread. Because these alternatives would require greater vegetation clearing along the transmission line corridor, weed spread associated with such clearing would be greater in these alternatives than Alternative B. MMC's weed control program described in Alternative 2 and modified in Alternative 3 would minimize weed infestations on lands disturbed by the transmission line facilities. BPA's plan to conduct a noxious weed survey at the proposed Sedlak Park Substation Site before and after construction of the substation and its weed control program would minimize noxious weeds at the site. MMC would coordinate with the Forest Service Weed Specialist for use of biocontrol agents as they become available. MMC and BPA would not be required to control other introduced species.

3.22.4.4.8 Effectiveness of Agencies' Proposed Mitigation

The agencies' modifications to MCC's weed control program would be effective in minimizing weed infestations on lands disturbed by the mine and transmission line facilities.

3.22.4.4.9 Cumulative Effects

Past actions, particularly timber harvest, road construction, and fire suppression, coupled with human activity have resulted in the establishment of the existing noxious weed and other introduced species populations in the analysis area. All reasonably foreseeable future projects in the area that involve ground disturbances have the potential to spread and increase the number of noxious weeds and other introduced species. Any ground-disturbing activities, activities that involve large equipment, livestock grazing, or activities that increase motor access could increase spread of noxious weeds or introduce new invaders to the area. Noxious weed and other introduced species infestations could impact sensitive plant species. The construction of both the Montanore Project and the Rock Creek Project would increase the opportunity for noxious weeds to invade the CMW from the east and west. All reasonably foreseeable actions would be subject to existing Forest Service, state, and county-wide management practices, which have proven effective in slowing the spread of targeted noxious weeds. Native species are also affected by chemical weed control programs. The Forest Service and other land managers and owners are not required to control other introduced species.

3.22.4.4.10 Regulatory/Forest Plan Consistency

Mine Alternative 2 and transmission line Alternative B would not fully comply with the KFP and Executive Order 13112. MMC did not propose to implement all weed BMPs identified in Appendix A of the KNF Invasive Plant Management Final EIS (KNF 2007a). In the agencies' mine and transmission line alternatives, all weed BMPs discussed in section 2.5.3.2.5, *Noxious Weed Mitigation Measures* would be implemented, and would reduce the establishment and spread of noxious weeds, compared to Alternatives 2 and B. Weed BMPs and other measures described in section 2.5.3.2.5, *Noxious Weed Mitigation Measures* would address the treatment and control of noxious weeds throughout all mine facilities.

3.22.4.4.11 Irreversible and Irretrievable Commitments

All alternatives have the potential to increase noxious weed and other introduced species populations, which would displace native species, and result in an irreversible loss of plant species. Chemical weed control programs would also limit native species.

3.22.4.4.12 Short-term Uses and Long-term Productivity

All alternatives have the potential to increase noxious weed and other introduced species populations, which would displace native species, and reduce their long-term productivity. Chemical weed control programs would also limit native species' productivity.

3.22.4.4.13 Unavoidable Adverse Environmental Effects

A potential unavoidable increase in noxious weed and other introduced species populations would occur under all alternatives. Invasion of noxious weeds and other introduced species as well as spraying of noxious weeds with chemicals would result in the loss of some native plant species.

3.23 Wetlands and Other Waters of the U.S.

3.23.1 Regulatory Framework

Discharges of dredged or fill material into waters of the U.S. are regulated under the Clean Water Act by the Corps of Engineers. Waters of the U.S. are defined broadly in the Corps' regulations to include a wide variety of waters and wetlands. All water bodies in the analysis area are State waters. The Corps defines "wetlands" as those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas (33 CFR 328.3 (b)). Under natural conditions, waters of the U.S. provide food and habitat for fish and wildlife, flood protection, erosion control, water quality improvement, and opportunities for recreation (Adamus *et al.* 1991). The term "wetlands and other wetland waters of the U.S." includes both deep-water habitats (non-wetland) and special aquatic sites, which include wetlands (Environmental Laboratory 1987).

This section discusses wetlands and other waters of the U.S. found within the analysis area. In Montana, surface water is any water of the State at the surface of the ground, including but not limited to any river, stream, creek, ravine, coulee, undeveloped spring, lake, and other natural surface source of water regardless of its character or manner of occurrence (ARM 36.12.101). The Corps determines a water to be subject to its jurisdiction if the water body is a traditionally navigable water, relatively permanent water, or a wetland that directly abuts a traditionally navigable or relatively permanent water body, or, in combination with all wetlands adjacent to that water body, has a significant nexus with traditionally navigable waters (Corps and EPA 2007).

The Corps defines springs as "any location where there is artesian flow emanating from a distinct point at any time during the growing season" (Corps 2012). In Montana, a spring is defined as a hydrologic occurrence of water involving the natural flow of water originating from beneath the land surface and arising to the surface of the ground. Any disturbances within 100 feet of a spring are regulated by the Corps (Corps 2012).

All activities that result in the discharge of fill material into wetlands or other waters of the U.S. are regulated by the Corps. Based on a Supreme Court 2001 ruling, wetlands that are isolated from other waters of the U.S., and whose only connection to interstate commerce is use by migratory birds, do not fall under Corps' jurisdiction. Such wetlands are "isolated" or "non-jurisdictional" and these terms are used synonymously.

Projects subject to the Corps' jurisdiction also must comply with the 404(b)(1) Guidelines for discharge of dredged and fill material into wetlands and other waters of the U.S. (40 CFR 230). It is anticipated that one or more Montanore Project facilities would need a 404 permit from the Corps. The 404(b)(1) Guidelines specify "no discharge of dredged or fill material shall be permitted if there is a practicable alternative to the proposed discharge which would have less adverse effect on the aquatic ecosystem, so long as the alternative does not have other significant adverse environmental consequences." An alternative is considered practicable if "it is capable of being done after taking into consideration cost, existing technology, and logistics in the light of overall project purposes." Practicable alternatives under the Guidelines assume that "alternatives that do not involve special aquatic sites are available, unless clearly demonstrated otherwise." The Guidelines also assume that "all practicable alternatives to the proposed discharge which do not involve a discharge into a special aquatic site are presumed to have less adverse effect on the aquatic ecosystem, unless clearly demonstrated otherwise" (40 CFR 230).

Federal agencies have responsibilities to avoid, minimize, and mitigate unavoidable impacts on wetlands under Executive Order 11990. Executive Order 11990 requires federal agencies to "consider factors relevant to a proposal's effect on the survival and quality of the wetlands." Federal agencies must find that there is no practicable alternative to new construction located in wetlands, and that the proposed action includes all practicable measures to minimize harm to wetlands. Agencies may take into account economic, environmental and other pertinent factors in making this finding.

In 2008, the Corps and the EPA issued regulations (33 CFR 332 and 40 CFR 230 Subpart J) regarding compensatory mitigation requirements for losses of aquatic resources, such as wetlands. These regulations require in cases where appropriate functional or condition assessment methods or other suitable metrics are available, these methods should be used where practicable to determine how much compensatory mitigation is required. If a functional or condition assessment or other suitable metric is not used, a minimum one-to-one acreage or linear foot compensation ratio must be used. Before issuance of the 2008 regulations, the Corps in Montana used ratios for various mitigation types in determining compensation requirements (Corps 2005). The Corps developed a stream mitigation procedure for projects adversely affected streams in 2010 and revised it in 2013 (Corps 2013a).

The KNF amended the KFP to establish standards for wetlands under the INFS standards (USDA Forest Service 1995). INFS standards and guidelines apply to an area within 150 feet of a wetland greater than 1 acre in size. For a wetland less than 1 acre, INFS standards and guidelines apply to an area within 100 feet of a wetland in priority watersheds and within 50 feet of a wetland in non-priority watersheds.

3.23.2 Analysis Area and Methods

3.23.2.1 Analysis Area

The analysis areas are areas where potential direct or indirect effects on wetlands and other waters of the U.S. by any of the alternatives would occur. The analysis area is the same as the analysis area used for surface water hydrology (discussed in section 3.11.2, *Analysis Area*) and shown on Figure 76.

3.23.2.2 Baseline Data Collection

3.23.2.2.1 Wetland Delineation and Functional Assessment

Wetlands and other waters were delineated within the analysis areas between 2005 and 2009 (Westech 2005e, Geomatrix 2008b; Geomatrix 2009b) following Corps methods (Environmental Laboratory 1987). Wetland boundaries were flagged and delineated using a Global Positioning System (GPS) device. Waters of the U.S. not likely to be filled with dredged or fill material, or sites where GPS coverage was lacking, were delineated from aerial photo interpretation. This included wetlands along access roads and the transmission line corridor, and on private lands. In 2011, MMC completed an inventory of the physical, chemical and biological characteristics of headwater drainages that would be directly affected by the Poorman Impoundment (Kline

Environmental Research 2012). Modifications to the location of some of the drainages mapped from 2005 to 2009 were made based on the Kline inventory. Wetlands mapped along the previous drainage alignments are considered riparian corridor wetlands (Figure 87) and were used in the impact calculation.

Wetland delineations were not completed for Alternative E-R - West Fisher Creek Alternative, a segment of Alternative D-R - Miller Creek Alternative in upper Miller Creek, segments of Alternative C-R - Modified North Miller Creek Alternative where they differ from Alternative B, and the segment in Alternatives C-R, D-R, and E-R from the Sedlak Park Substation north to where the alignment crosses Alternative B. Wetland delineations also would be needed at sites proposed in the agencies' fisheries and wildlife mitigation measures, such as road crossings where culverts would be removed.

Wetlands near the Sedlak Park Substation site were not delineated according to the 1987 Corps of Engineers Wetlands Delineation Manual. Instead, BPA environmental staff identified wetland boundaries based on the presence of hydric soil boundaries, secondary hydrologic indicators, and wetland vegetation. Wetland boundaries were recorded using a GPS device. GPS data were used by BPA to develop a substation design that would avoid and minimize impacts on wetlands and waters of the U.S. (BPA 2008).

An assessment of the jurisdictional status of each wetland was made during the wetland delineations. Wetlands and other waters were assigned as either jurisdictional wetlands, jurisdictional non-wetland waters of the U.S., or isolated wetlands. Isolated wetlands are not connected by surface flow to jurisdictional waters of the U.S. Non-wetland waters of the U.S. were delineated to the ordinary high water mark where stream channels had a defined bed and bank during the 2005 delineation (Westech 2005e). Non-wetland waters of the U.S. in the Poorman Impoundment Site were updated based on the 2011 stream survey (Kline Environmental Research 2012). The 2005 wetland delineation (Westech 2005e) and the 2009 wetland delineation (Geomatrix 2009b) have been subject to a preliminary jurisdictional determination by the Corps (Corps 2005a, 2008b). An approved jurisdictional determination of isolated wetlands in the Poorman Impoundment Site has been completed (Corps 2008c, 2014). In 2013, the Corps issued an updated preliminary jurisdictional determination of wetlands and non-wetland waters within the Poorman Impoundment Site (Corps 2013b). The Corps determined that short reaches of four drainages in the Poorman Impoundment Site lacked a defined channel and were non-jurisdictional. Other reaches were determined to be relatively permanent waters, which are subject to Corps jurisdiction (Figure 87). In the effects analysis, the lead agencies used the Corps' preliminary and approved jurisdictional determinations of the sites. The jurisdictional status of the wetlands and other waters of the U.S. is preliminary and impacts may change during the 404 permitting process.

Between 2005 and 2008, functions and services for wetlands within the analysis area were evaluated using the 1999 MDT Montana Wetland Assessment Method (Berglund 1999). In 2010, wetland functional assessments were revised following the 2008 MDT Montana Wetland Assessment Method (MDT method) (Berglund and McEldowney 2008; Geomatrix 2010d). The MDT method uses a classification system that combines the USFWS classification system (Cowardin *et al.* 1979) with a hydrogeomorphic (landscape position) approach (Brinson 1993). The MDT method provides a landscape context to the USFWS classification. The MDT method classifies wetlands as Category I, II, III, or IV. Category I wetlands are exceptionally high quality wetlands and are generally rare to uncommon. Category II wetlands are more common than

Category I wetlands, and provide habitat for sensitive plants and animals. Category III wetlands are more common than Category II or I wetlands, generally less diverse, and are often smaller than Category II or I wetlands. Category IV wetlands are generally small, isolated, and lack vegetative diversity. These wetlands provide minor wildlife habitat.

3.23.2.2.2 Hydrologic Assessment

Groundwater Levels – Poorman Impoundment Site

MMC collected groundwater data from several piezometers installed in wetlands within the Poorman Impoundment Site to provide information on seasonal and yearly variations and insight into hydrologic support of wetlands. In 2011, MMC installed three shallow piezometers in wetland WUS-15 and one nested pair in WUS-17. The three piezometers installed in the WUS-15 wetland area are not adjacent to each other because groundwater was below the maximum depth that could be augered or driven by the piezometers after initial installation. The three piezometers in wetland WUS-15 were spaced apart to assess depth to groundwater at different locations. One shallow piezometer was also installed in isolated wetland WUS-30 to a depth of 3.0 feet. In 2012, two additional piezometers were installed in WUS-17; one to a depth of 6 feet and the other to a depth of 11.8 feet. One piezometer was installed in WUS-1 (5.2 feet deep) and WUS-2 (6.3 feet deep). Water levels in each piezometer were measured periodically. To identify the source of the water, sampling and analysis of stable water isotopes (oxygen 18 and deuterium) of some of the piezometers was conducted.

Wetland Landscape Position Assessment

To determine the potential hydrologic support for wetlands without groundwater wells in the Poorman and Little Cherry Creek Impoundment sites and to assist in determining indirect effects on wetlands, ERO reviewed the topographic position of wetlands in relation to light detection and ranging (LiDAR) optical remote sensing data from which topographic maps were produced in 2012 (ERO Resources Corp. 2013). MMC's LiDAR mapping has elevation contours of 2 feet. Wetland mapping used in this assessment was completed by Westech Environmental Services, Inc. (2005) and Geomatrix (2008) for the Little Cherry Creek Impoundment Site and by Geomatrix (2009) for the Poorman Impoundment Site, with supplemental stream mapping in the Poorman Impoundment Site provided by Kline Environmental Research (2012). ERO assumed that wetlands located in topographic depressions and closed basins are primarily surface water supported. These wetlands collect and hold precipitation, snow melt, and surface water drainage into the basin. Wetlands on a slope that are either isolated, associated with a channel, or associated with a spring are assumed to be primarily groundwater supported. These wetlands are constantly draining downslope and will not retain hydrologic support without additional groundwater.

3.23.2.2.3 Libby Creek, East Fork Bull River, and East Fork Rock Creek

Cross sections on Libby Creek (1 mile upstream of Little Cherry Creek), East Fork Rock Creek (1 mile upstream of the confluence with the West Fork Rock Creek), and East Fork Bull River (at the confluence with Isabella Creek) were established to assess indirect effects on wetland vegetation from changes in stream flow (ERO Resources Corp. 2012a). Presence of wetland or riparian vegetation and the width of the vegetation zone along each stream at the cross sections were noted. The relationship between wetted perimeter and flow was determined to estimate changes to wetland vegetation.

3.23.2.3 Impact Analysis

3.23.2.3.1 Direct Effects

Impacts of the mine alternatives on wetlands and streams were determined by calculating the number of acres that would be disturbed. For analysis purposes, the lead agencies used a disturbance area to assess effects on surface resources. The disturbance area surrounding both impoundment areas encompassed most of the wetlands and streams downstream of the impoundment areas. Within the disturbance areas are facility boundaries that include the footprint of the impoundment, dam, seepage collection pond, diversion channel, borrow area, soil stockpiles, and roads. Wetlands within the facility boundary would be filled by project activities while some wetlands and other waters in the disturbance boundary that are not within the facility boundary may be avoided during final design. The effects within the disturbance boundary are presented as the total potential effects for this EIS.

Wetland mapping did not distinguish open water channels from adjacent wetlands along stream channels. For example, wetlands along Little Cherry Creek as well as the Little Cherry Creek channel were mapped as riverine wetlands. To differentiate effects on wetlands from open water, open water and channel width were subtracted from the wetland information provided by Westech and Geomatrix and incorporated into the impact analysis. An average channel width of 5.5 feet was used for Little Cherry Creek and an average width of 3 feet was used to calculate riparian corridor wetlands for the four drainages within the Poorman Impoundment Site (Geomatrix and Kline Environmental Research 2011).

As a basis for comparing transmission line alternatives, acreage of all wetlands and streams within the transmission line clearing area was calculated. Direct effects on wetlands and streams are expected to be mostly avoided by placement and location of the substation, loop line, and transmission structures outside of wetlands and streams. Unavoidable direct effects on wetlands would be determined during final design.

3.23.2.3.2 Indirect Effects

Indirect effects on wetlands near the impoundment sites from a pumpback well system were assessed by determining the primary supportive hydrology of wetlands (groundwater or surface water) (ERO Resources Corp. 2013b) and determining which groundwater-supported wetlands would be potentially affected by groundwater drawdown from a pumpback well system. In its analysis, ERO assumed that wetlands located in topographic depressions and closed basins were primarily surface water supported. These wetlands collect and hold precipitation, snow melt, and surface water drainage into the basin. Wetlands on a slope that are either isolated, associated with a channel, or associated with a spring were assumed to be primarily groundwater supported. These wetlands are constantly draining downslope and will not retain hydrologic support without additional groundwater.

MMC evaluated a pumpback well system for the Poorman Impoundment in Alternative 3 using a 3D groundwater model (Geomatrix 2010c). The lead agencies assumed any wetland within the 1-foot drawdown contour was potentially at risk of losing hydrologic support. The drawdown from the Poorman Impoundment would extend to Little Cherry Creek on the north and 5,000 feet to the south of the dam crest (Figure 73). A pumpback well system for the Little Cherry Creek impoundment in Alternatives 2 and 4 was not modeled. The lead agencies assumed drawdown from a pumpback well system in the Little Cherry Creek impoundment in Alternatives 2 and 4, if installed, 4 would extend from Bear Creek to 5,000 feet to the south of the dam crest.

The *Geology and Geochemistry and Groundwater Hydrology* sections discuss the geology of the impoundment sites. A low permeability bedrock ridge separates groundwater flow between the watershed of Little Cherry Creek and those of Drainages 5 and 10 in the Poorman Impoundment Site (Figure 66). NewFields (2014a) concluded that the bedrock ridge would limit drawdown in the Little Cherry Creek watershed, but drawdown could still extend between watersheds unless the bedrock ridge provided a complete barrier to cross-boundary groundwater flow. Wetland impacts were distinguished based on the separation of the wetland by the bedrock ridge from the impoundment. All available geologic and hydrogeologic data from the Little Cherry Creek and in the Poorman impoundment areas were reviewed and discussed in detail by NewFields (2014a).

In 2009, MMC completed a GDE inventory focusing on areas at or below about 5,600 feet on the north side of the Libby Creek watershed (Geomatrix 2009). Additional inventory in the Libby Creek drainage was conducted in 2010. The additional inventory consisted of inventorying GDEs identified in 2009 (Geomatrix 2010). An inventory of other mine areas, such as the Ramsey Creek, East Fork Rock Creek and East Fork Bull River drainages, was conducted in 2012. Additional areas were inventoried by MMC in 2013, including upper Libby Creek, upper Ramsey Creek and Ramsey Lake, upper East Fork Bull River at and above St. Paul Lake, upper East Fork Rock Creek at and above Rock Lake, and the Libby Lakes basin (MMC 2014d). In 2013, MMC surveyed GDEs, measured flows, collected water quality samples and stable isotope samples, measured groundwater levels in piezometers, and completed vegetation surveys at upper watershed area springs, seeps, streams and lakes, mostly within the CMW.

3.23.3 Affected Environment

3.23.3.1 Wetlands and Streams

In the analysis area, wetlands are primarily located adjacent to low terraces, overflow channels, and scoured depressions along perennial streams. Wetlands are also found in depressions and low gradient swales in the two tailings impoundment sites (Figure 87). Fisher River, Libby Creek, Ramsey Creek, Poorman Creek, Little Cherry Creek, Bear Creek, Howard Creek, Miller Creek, West Fisher Creek, Hunter Creek, Sedlak Creek, and other unnamed drainages are likely waters of the U.S. Section 3.11.3.2.1*, Watershed Descriptions* provides additional descriptions of these drainages. Springs, seeps, and runoff from snowmelt and precipitation result in soil saturation or inundation during spring and early summer. Sidehill and toeslope seeps are present along portions of Little Cherry Creek. These seeps range from small discrete trickles to more extensive zones of saturation along slopes where the seepage zone may extend for more than 100 feet. Sidehill and toeslope seeps are generally saturated late into the growing season.

3.23.3.1.1 Wetland Types

Forest-dominated wetland types (riverine palustrine forested, slope palustrine forested, and depressional palustrine forested) are primarily found along stream corridors and seeps, mostly in the Little Cherry Creek drainage. This wetland type is dominated by western redcedar, western hemlock, and Engelmann spruce. Understory species include devil’s club, lady fern, oakfern, arrowleaf groundsel, and common horsetail (Westech 2005e and Geomatrix 2009b).

Scrub-shrub dominated wetlands (slope palustrine scrub-shrub, depressional palustrine scrub-shrub, and riverine palustrine scrub-shrub) support Douglas spirea, thinleaf alder, alder buckthorn, and common snowberry. Understory species include inflated sedge, brown bog sedge, bluejoint reedgrass and common horsetail. Scrub-shrub-dominated wetlands are found along drainages where trees have been removed by logging, around depressions, in logged swales with poor drainage, and in oxbows of the Fisher River (Westech 2005e; Geomatrix 2009b). Scrub-shrub wetlands are found in the Little Cherry Creek, Bear Creek, and Rock Creek drainages.

Herbaceous-dominated wetlands (slope palustrine emergent and depressional palustrine emergent) are wet depressions or slope areas with poorly drained soils. Sedges such as inflated sedge, beaked sedge, and knot-sheath sedge are typically the dominant species with horsetails, rushes, and other graminoids being co-dominants (Westech 2005e; Geomatrix 2009b). Herbaceous-dominated wetlands occur within the Little Cherry Creek and Poorman Impoundment Sites.

3.23.3.1.2 Wetland Functional Assessment

Category II and III wetlands are the most common functional category and are found throughout the analysis areas. Category I, II, III, and IV wetlands are found along Little Cherry Creek in the Little Cherry Creek Impoundment Site. Category IV wetlands are uncommon and are associated with Little Cherry Creek. Category II and III wetlands are found in the Poorman Impoundment Site (Geomatrix 2010d).

Category II wetlands in the analysis area had high functional ratings for structural diversity, general wildlife habitat, known or potential habitat for special-status wildlife species, and sediment/toxicant removal. Category III wetlands are most common in the analysis area and are present in areas that previously have been logged, and usually are seasonally flooded due to spring snow melt and precipitation.

3.23.3.1.3 Springs

Numerous springs are located in the analysis area. Spring types and locations are described in section 3.10.3, *Affected Environment* in the *Groundwater Hydrology* section. Spring 26 is located at the upper end of a large slope wetland in the Poorman Impoundment Site. Based on a review of data collected on tritium and stable isotopes of oxygen and hydrogen for Spring 26 (Gurrieri 2013; NewFields 2013a), the water from Spring 26 appears to be older than 1950, suggesting the water source is likely a deep aquifer. The location of the spring and wetland on a slope provides further evidence that the water source of the wetland is groundwater (Gurrieri 2013; ERO Resources Corp. 2013). Data from other springs within the Poorman Impoundment Site were not collected.

3.23.3.1.4 Libby Creek, East Fork Bull River, and East Fork Rock Creek

Data collected by KNF on cross sections on Libby Creek, East Fork Bull River, and East Fork Rock Creek indicate these streams are dominated by medium to large cobble and are slightly to moderately entrenched. Vegetation along the banks of Libby Creek is mostly dominated by cottonwood, Douglas-fir, spruce, cedar, alder, and willow. At the cross sections of the East Fork Bull River and East Fork Rock Creek, the vegetation is dominated by western red cedar, mountain maple, black cottonwood, Western hemlock, Pacific yew and grand fir with Devil's club in the understory. The dominant species and the cobbly soils are more characteristic of riparian vegetation. Due to the lack of soil and dominance of species that have a wide moisture tolerance, wetlands that meet the criteria of the Corps are likely absent from the banks of the streams. Because vegetation along these major streams is more characteristic of riparian vegetation, these streams are discussed in section 3.22, *Vegetation* and no further discussion is provided in this section.

3.23.3.1.5 Groundwater Dependent Ecosystems

During the 2013 inventory, MMC identified wetlands, mostly associated with springs or seeps, near lower Libby Lake, upper East Fork Bull River Tributary drainage above Saint Paul Lake, upper East Fork Rock Creek drainage, and upper Libby Creek drainage (MMC 2014d). Wetlands near lower Libby Lake are supported by four separate seeps and have distinctive wetland vegetation including moss and algae. In the upper East Fork Bull River tributary drainage the GDE is a large seep/pond/wetland complex. The upper East fork Rock Creek drainage, a series of seeps run over bedrock and limited wetland vegetation to establish. In the upper Libby Creek drainage, springs and seeps provide the supportive hydrology for wetland with diverse wetland vegetation. Additional wetlands, seeps, and springs may be identified in future inventories if they were required to meet the agencies' requirements described in Appendix C. Effects on these resources would be identified through monitoring described in Appendix C.

3.23.4 Environmental Consequences

3.23.4.1 Alternative 1 – No Mine

The No Mine Alternative would not disturb or affect any wetlands or other waters of the U.S.

3.23.4.2 Alternative 2 – MMC's Proposed Mine

3.23.4.2.1 Direct Effects

Mine Facilities

Alternative 2 would have 35.6 acres of jurisdictional wetlands within the disturbance area, which includes 25.0 acres within the facility boundary (Table 184). Most of these wetlands would be forested wetlands located in the proposed Little Cherry Creek Tailings Impoundment Site. Functional Category I, II, III, and IV wetland types in the Little Cherry Creek Tailings Impoundment Site would be affected. About 1.1 acre of isolated wetlands found in small scattered locations in the Little Cherry Creek Tailings Impoundment Site would be within the disturbance area. These isolated wetlands are generally small depressions resulting from logging activity (Westech 2005e). About 28,355 linear feet of streams would be within the disturbance area of Alternative 2, while 19,700 linear feet would be within the facility boundary (Table 184). Streams and wetlands in Ramsey Creek would be bridged for access to the Ramsey Plant site and would not be affected.

Table 184. Wetlands and Streams within Mine Alternative Disturbance Areas.

The jurisdictional status of the wetlands and streams is based on the Corps' preliminary and approved jurisdictional determinations (Corps 2008c, 2013b, 2014). Impacts by jurisdictional status may change during the 404 permitting process.

Units for areas are rounded to the nearest 0.1 acre; units for stream length are rounded to the nearest whole number; subtotals may vary by 0.1 acre due to rounding.

†The adits would not affect any wetlands or streams in any alternative; although bridges would be constructed for road crossings on Ramsey, Poorman, and Bear creeks and would likely not affect wetlands or streams Effects are included under the disturbance boundary effects.

§Area of streams has been subtracted from the area of wetlands.

*Impoundment site includes the impoundment footprint, dam, seepage collection pond, diversion channel, borrow area, soil stockpiles, and some roads.

Effects of Mitigation Measures

This section describes the effects of MMC's mitigation measures on wetlands and other waters of the U.S. The agencies' evaluation of MMC's mitigation plan for wetlands and other waters of the U.S. is discussed in 3.23.4.10, *Proposed Mitigation and Monitoring Plans*. As part of Alternative 2, one of the possible fisheries mitigation projects proposed by MMC would be to conduct a sediment-source inventory in the watershed, and stabilize, recontour, and revegetate priority source areas, which are typically roadcuts in Libby, Hoodoo, Poorman, Midas, and Crazyman creeks. Wetland delineations at these sediment source areas have not been completed. Any wetlands and waters of the U.S. disturbed during the implementation of this mitigation are not listed in Table 184. If implemented, this mitigation in the short term would increase sedimentation in area streams and adjacent wetlands and waters of the U.S. Over the long term, this mitigation may increase the function and services of any associated wetlands and would decrease sediment delivery to waters of the U.S.

3.23.4.2.2 Indirect Effects

NEPA regulations define indirect effects as "…effects, which are caused by the action and are later in time or farther removed in distance, but are still reasonably foreseeable." (40 CFR

1508.8). The discussion of indirect effects on wetlands in Alternatives 2, 3, and 4 is consistent with the NEPA definition. Under the 404(b)(1) Guidelines (40 CFR 230.11(h)(1)), "secondary effects are effects on an aquatic ecosystem that are associated with a discharge of dredged or fill materials, but do not result from the actual placement of the dredged or fill material. Information about secondary effects on aquatic ecosystems shall be considered before the time final section 404 action is taken by permitting authorities." The Corps indicated to the KNF that mine dewatering and operation of a pumpback well system are not within its scope of analysis and the effects of these activities will not be considered in its 404 permit decision. Consequently, the Corps will not require mitigation for indirect effects of mine dewatering and operation of a pumpback well system.

Mine Dewatering

Indirect effects on wetlands, springs, and seeps may occur during mine dewatering. The indirect effect on wetlands, spring, and seep habitat overlying the mine would be the same in all mine action alternatives and difficult to predict (see section 3.10.4.2.1, *Evaluation through Operations Phases*). The effect on plant species, functions, and services associated with the affected wetlands, springs, or seeps by a change in water level would be best determined by relating plant species with water abundance and quality for monitoring and evaluation. Alternative 2 does not include a survey of plant species abundance (all species) before activity and subsequent plant species abundance and water monitoring of GDEs overlying the mine. Without this type of monitoring, mining-induced changes in water level or quality may result in an unidentified loss of species, functions, and services associated with the affected wetlands, springs, or seeps.

In the upper watershed, wetlands at Rock Creek Meadows are not expected to be indirectly affected by mining or dewatering. The 3D model predicted the greatest surface flow reduction of 0.43 cfs on East Fork Rock Creek where it enters Rock Creek Meadows 16 years after mine closure (Klepfer Mining Service 2012). Although this would be a 20 percent reduction in baseflow, a perennially high water table and other tributaries that flow into Rock Creek Meadows that would not be affected by mining provide the primary hydrologic support for wetlands at Rock Creek Meadows.

Watershed Modification and Seepage Control Systems

Several wetlands and springs are present between the proposed Little Cherry Creek Tailings Impoundment and Libby Creek. Precipitation and runoff captured by the tailings impoundment and the Seepage Collection Dam would no longer flow to the former Little Cherry Creek. The pumpback well system if installed to collect seepage not collected by the underdrain system would likely lower groundwater levels and reduce groundwater discharge to springs, seeps, and wetlands downgradient of the impoundment. Flow below the Seepage Collection Dam in the former Little Cherry Creek channel would be substantially reduced. The agencies estimated the following indirect effects on streams and wetlands below the disturbance boundary:

- Reduced flow to 2,757 linear feet of Little Cherry Creek below the Seepage Collection Dam to Libby Creek all on private land. 290 linear feet occur within the disturbance boundary and are accounted for in Table 184. The 2,467 linear feet of Little Cherry Creek that would be indirectly affected are not accounted for in Table 184 or Table 185.
- Reduced flow to 1,395 linear feet of a small tributary to Little Cherry Creek below the disturbance boundary all on private land. This indirect effect has not been accounted for in Table 184 or Table 185.

- Reduced flow to 987 linear feet of a tributary to Libby Creek below the disturbance boundary on National Forest System land and 549 linear feet on private land. These indirect effects have not been accounted for in Table 184 or Table 185.
- The combined total of indirect effects on the drainages that occur outside of the disturbance boundary not accounted for in Table 184 or Table 185 would be 5,398 linear feet, of which 987 linear feet would be on National Forest System land.
- Reduced flow to 0.4 acre of wetland associated with the drainages below the disturbance boundary that occur on National Forest System lands. Another 1.3 acre of wetlands associated with the drainages below the disturbance boundary are on private land. These indirect wetland effects have not been accounted for in in Table 184 or Table 185.

In Alternative 2, MMC committed to implementing seepage control measures at the impoundment, such as pumpback recovery wells, if required to comply with applicable standards. Seepage pumpback wells could be installed along the downstream toe of the tailings dam. The wells may require active pumping, depending on the artesian pressures within the wells (Klohn Crippen 2005). A subsurface bedrock ridge occurs south of the impoundment dam (see discussion in the *Groundwater Hydrology* section). If MMC installed a pumpback well system, the effects on groundwater from pumping may be reduced or eliminated south of the bedrock ridge. Based on the assessment of groundwater-supported wetlands within a potential drawdown area north of the bedrock ridge from the disturbance boundary to Bear Creek, no jurisdictional wetlands on National Forest System land would be indirectly affected (Table 185). About 1.2 acres of jurisdictional wetland north of the ridge on National Forest System land would require more data to determine supportive hydrology. South of the ridge, an additional 0.6 acre of jurisdictional ground water-supported wetland occurs on National Forest System land. Disregarding the bedrock ridge, a total of 1.8 acres of jurisdictional wetlands and 0.2 acre of isolated wetland on National Forest System land would be potentially indirectly affected. Wetlands north of the Little Cherry Creek Impoundment Site and south of Bear Creek have not been delineated for Alternative 2; therefore, the number of wetland acres potentially indirectly affected may be greater than what is shown in Table 185.

MMC would monitor effects on existing wetlands downstream of the tailings impoundment. Monitoring of the downstream wetland areas would be completed annually for the first 5 years of mine operation. If functions and services of downstream wetlands were adversely affected, MMC, in cooperation with the lead agencies and the Corps, would develop additional wetland mitigation. MMC did not propose monitoring wetlands north or south of the impoundment. MMC’s proposed monitoring would not adequately detect potential changes to wetlands from the operation of the impoundment and pumpback well system.

Temporary indirect effects on wetlands and streams may occur during construction of the proposed Little Cherry Creek Tailings Impoundment and associated facilities due to increased sediment contributions to wetlands and streams Proposed BMPs would reduce or eliminate sediment contributions to wetlands and streams.

The flow in the unnamed drainages into which upper Little Cherry Creek would be diverted (Drainages 5 and 10) would increase and would change to perennial flow throughout their length. The drainages are not large enough to handle the expected flow volumes and downcutting and increased sediment delivery to Libby Creek would occur as the channel stabilized. Where possible, MMC would construct some bioengineering and structural features in the two drainage channels to reduce flow velocities, stabilize the channels, and create fish habitat. Short sections of these two channels are very steep, and it may be difficult to access such sections to complete any channel stabilization work. In addition, some sections of these two channels have very thick vegetation that may require clearing, which may create erosion and increase sediment delivery to the channels. Over time, the channels would stabilize and provide increased water for wetlands adjacent to the channels. The section that is currently intermittent probably would support wetlands where flow became perennial.

Table 185. Potential Indirect Wetland Effects from Groundwater Drawdown in the Tailings Impoundment Area.

3.23.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

3.23.4.3.1 Direct Effects

Mine Facilities

Alternative 3 would have 9.2 acres of jurisdictional wetlands, 3.5 acres of isolated wetlands, and 14,331 linear feet of streams within the disturbance area (Table 184). Functional Category II and III wetland types would be affected in the Poorman Impoundment Site. Because the Poorman Impoundment would not require diversion of a perennial stream, Alternative 3 would affect fewer wetlands compared to Alternatives 2 and 4 (Figure 87). Effects on wetlands within the facility boundary only, including additional access roads, would be 8.8 acres. These wetlands would not be filled by the tailings but are within the disturbance area and likely would be filled by access roads or other project facilities. During final design, MMC would avoid wetlands to the extent practicable.

Effects of Mitigation Measures

This section describes the effects of the agencies' mitigation measures on wetlands and other waters of the U.S. The agencies' evaluation of the agencies' mitigation plan for wetlands and other waters of the U.S. is discussed in 3.23.4.10, *Proposed Mitigation and Monitoring Plans*. MMC would continue to plow the Libby Creek Road (NFS road #231) and the Upper Libby Creek Road (NFS road #2316) year-round during the 2-year evaluation program and the 1-year period during reconstruction of the Bear Creek Road. Culverts along all access roads that pose a substantial risk to riparian conditions would be replaced as necessary to comply with INFS standards and Forest Service guidance, such as fish passage or conveyance of adequate flows (USDA Forest Service 1995, 2008a). Any work in a RHCA along an access road would be completed in compliance with INFS standards and guidelines. The mitigation would increase sedimentation in area streams and adjacent wetlands and waters of the U.S. in the short term. Over the long term, the mitigation may increase the function and services of any associated wetlands and would decrease sediment delivery to waters of the U.S.

The Grizzly Bear Mitigation Plan for Alternative 3 would include 20.3 miles of proposed access changes during the Evaluation Phase and up to 20.1 miles of proposed access changes during the Construction Phase in the Rock Creek, Libby Creek, and Miller Creek watersheds (Figure 35). The Plan also would require MMC to acquire 5,387 acres of land for habitat replacement. Habitat enhancement, such as access changes and trail conversions, may be implemented on the acquired lands. Wetland delineations along the roads and trails proposed for access changes have not been completed. MMC would build and maintain gates or barriers on the roads, and complete other activities so that the roads would either be removed from service or cause little resource risk if maintenance were not performed on them during the operation period of the mine and before their future need. In most cases, culverts would be removed; such removals would occur in active stream channels requiring instream work, structure placement, and fill removal. The effect would be the same as described for road improvements along the Libby Creek Road and the Upper Libby Creek Road.

Post-Closure, a channel would be excavated through the tailings and Saddle Dam abutment to route runoff from the site toward a tributary of Little Cherry Creek. The increased flow would provide support to wetlands adjacent to Little Cherry Creek. Wetlands may develop in the unnamed tributary of Little Cherry Creek below the Saddle Dam abutment.

3.23.4.3.2 Indirect Effects

Mine Dewatering

Indirect effects on wetlands, springs, and seeps may occur during mine dewatering. In Alternative 3, MMC would complete a GDE inventory and conduct GDE monitoring in an area overlying the proposed mine and adits to evaluate indirect wetland effects (see section C.10, *Water Resources* of Appendix C). The inventory, which began in 2009, includes a vegetation survey to describe and document existing vegetation characteristics and establish a prevalence index used by the Corps to determine wetland vegetation (Corps 2008d). The prevalence index would be used to assess changes in vegetation composition and if a loss of wetland species was occurring. The monitoring would not alter the effect of Alternative 3 but would assist in determining if an impact was occurring and the scale of any impact. Other temporary indirect effects of construction would be the same as Alternative 2.

Watershed Modification and Seepage Control Systems

About 0.2 acres of riparian corridor wetlands occur below the disturbance boundary on Drainages 3 and 14. These riparian corridor wetlands would be indirectly affected by changes in hydrology related to a change in their watershed and filling of perennial springs. The 0.2-acre of indirect wetland effect would be mitigated at the Swamp Creek site.

Segments of Drainages 3, 5, 10, and 14 are found below the impoundment (Figure 87). Intermittent and/or perennial flow in the channels would likely be either reduced or eliminated. The agencies estimated the following indirect effects to streams in the Poorman Impoundment Site:

- Reduced flow to 2,326 linear feet of Drainage 3 between the Tailings Impoundment and Libby Creek. Most of this reach has persistent flow. 1,164 linear feet are within the disturbance boundary and have been accounted for in Table 184; 1,162 linear feet of Drainage 3 are outside of the disturbance boundary and not accounted for in Table 184.
- Reduced flow to 559 linear feet of Drainage 5 between the Tailings Impoundment and the Seepage Collection Pond. This reach currently has persistent flow. All of this effect is accounted for in the disturbance area impacts shown in Table 184.
- Reduced flow in 1,364 linear feet of Drainage 10. Of the 1,364 feet, 235 linear feet are below the disturbance boundary and have not been accounted for in Table 184. 1,129 linear feet are within the disturbance boundary and have been accounted for in Table 184.
- Reduced flow in 3,963 linear feet of Drainage 14 between the Tailings Impoundment and Libby Creek. This reach currently has an estimated annual flow duration of 117 days. The disturbance area impacts shown in Table 184 accounts for 633 linear feet of this effect.
- The combined total of indirect effects on the four drainages that occur outside of the disturbance boundary would be 4,727 linear feet.

MMC used a 3D model to predict the effect of the pumpback wells on the impoundment site's hydrology. To the north, the model predicted that the drawdown from the wells would extend to Little Cherry Creek, potentially affecting wetlands between the Poorman Impoundment Site and Little Cherry Creek. NewFields concluded that the bedrock ridge would limit drawdown in the

Little Cherry Creek watershed, but drawdown could still extend between watersheds unless the bedrock ridge provided a complete barrier to cross-boundary groundwater flow. According to NewFields (2014a), perched groundwater conditions occur beneath most wetlands in Little Cherry Creek and in the Poorman impoundment areas and the hydrologic support for the wetlands appears to be direct precipitation and upgradient runoff water that infiltrates into the subsurface. NewFields concluded the operation of the pumpback wells would have little or no effect on most wetlands in the Little Cherry Creek watershed.

Section 3.10.4.2 indicates operation of a pumpback well system may not affect groundwater levels and five of the springs south of Little Cherry Creek because of an apparent subsurface bedrock ridge that separates groundwater flow between the watershed of Little Cherry Creek from those of Drainages 5 and 10 in the Poorman Impoundment Site (Chen Northern 1989). Because geologic and hydrologic data from the area between the Little Cherry Creek and Poorman drainages are limited, they are not sufficient to eliminate the possibility of the pumpback well system adversely affecting surface resources, particularly groundwater-supported wetlands. The agencies are not proposing mitigation for indirect wetland effects from the pumpback wells until more investigation indicates that they would be adversely affected. The rationale for not proposing mitigation for indirect wetland effects from the pumpback wells is discussed in a following section (*Mitigation for Other Potential Indirect Effects*).

In 2012, MMC installed shallow piezometers in each of four wetlands (LCC-29, LCC-35A, LCC-36, and LCC-39A) south of Little Cherry Creek. One piezometer was installed in wetlands LLC-29 and LLC-36, two piezometers were installed in wetland LLC-35A, and three piezometers were installed in wetland LLC-39A. Water levels for five of the piezometers were measured in November 2012, two of which were dry. Water levels in the piezometers would continue to be measured monthly April through September. The purpose of the monitoring would be to assess effects on wetlands. Vegetation in these four wetlands also would be monitored, following the methods used for the GDE monitoring (see section C.10.4.2, *Groundwater Dependent Ecosystem Monitoring* in Appendix C). The monitoring would continue through the Closure Phase as long as the pumpback well system operated.

Springs SP-14 and SP-15 (Figure 70) adjacent to the impoundment site would be monitored for flow. The flow of each spring would be measured twice, once in early June or when the area was initially accessible, and once between mid-August and mid-September during a time of little or no precipitation. The monitoring would begin 1 year before construction and continue through the Closure Phase as long as the pumpback well system operated. The most accurate site-specific method for measuring spring flow would be used.

3.23.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

3.23.4.4.1 Direct Effects

Mine Facilities

Alternative 4 would directly affect 36.7 acres of jurisdictional wetlands, 1.2 acres of isolated wetlands, and 27,753 linear feet of streams within the disturbance area (Table 184). Most effects would be in the Little Cherry Creek Impoundment Site. Functional Category I, II, III, and IV wetlands would be affected in the Little Cherry Creek Impoundment site.

Effects of Mitigation Measures

The same mitigation measures described in Alternative 3 would be implemented in Alternative 4, except for the post-closure development of a channel to route runoff from the site toward a tributary of Little Cherry Creek. Any wetlands and streams disturbed during the implementation of the mitigation measures are not shown in Table 184. In the short term, these activities would increase sedimentation in area streams and adjacent wetlands and streams. After the activities were completed, and the roads became stabilized, these mitigation measures would increase the function and services of any associated wetlands and would decrease sediment delivery to streams. Access changes for grizzly bear mitigation would be the same as Alternative 3; MMC would acquire 6,151 acres of land for mitigation. The agencies' mitigation plan for wetlands and other waters of the U.S. is discussed in section 3.23.4.10, *Proposed Mitigation and Monitoring Plans*.

3.23.4.4.2 Indirect Effects

Mine Dewatering

To account for indirect effects on wetlands, springs, and seeps from mine dewatering, a GDE inventory of an area overlying the mine area, subsequent monitoring of GDEs, and implementation of any mitigation would be completed in Alternative 4, as described in Alternative 3.

Watershed Modification and Seepage Control Systems

Flow from springs SP-02, SP-10, S-12, SP-14, SP-15, and SP-29 (shown on (Figure 40) would be measured twice, once in early June when the area was initially accessible, and once between mid-August and mid-September 1 year before construction began. Springs SP-02 and SP-15 would not be monitored if they were covered by impoundment facilities. Samples from these springs would be collected 1 year before construction and analyzed for selected water quality parameters. Sampling would be repeated every 2 years until tailings disposal ceased. At each spring, a vegetation survey would be completed 1 year before construction; the use of a prevalence index to monitor changes in plant species would be the same as Alternative 3.

MMC would monitor three wetlands, LCC-24, LCC-25, and LCC-39 (shown on Figure 40), if these wetlands were not filled by project activities. MMC would use the procedures established for monitoring wetland mitigation sites described in Alternative 3 to assess vegetation characteristics and establish a prevalence index. A prevalence index would be used to assess changes in vegetation composition and to detect a loss of wetland species. Samples from any standing water in these three wetlands would be collected in mid-summer 1 year before construction began and analyzed for selected parameters. Sampling would be repeated in mid-summer every 2 years until tailings disposal ceased. The mitigation would not alter the effect of Alternative 4, but would assist in determining if an impact were occurring and the scale of any impact.

Other indirect effects would be similar to Alternative 2 but less than 0.1 acre of isolated groundwater-supported wetlands would potentially be affected by groundwater drawdown north of the ridge on National Forest System land. An additional 1.2 acres of wetlands would require additional data before determining if groundwater is the primary hydrologic support and would potentially be affected. Effects on stream channels and associated wetlands on National Forest System land below the Seepage Collection Pond would be the same as Alternative 2 except that 1,244 linear feet of channel (257 linear feet more than in Alternative 2) and 0.7 acre of wetland (0.3 acre more than in Alternative 2) would be indirectly affected below the disturbance boundary. On private land, the total linear feet of channel that would be indirectly affected would be 4,464 linear feet (53 linear feet more than in Alternative 2) and the total acres of wetland would be 1.3 (same as Alternative 2).

3.23.4.5 Alternative A – No Transmission Line

Because construction of the transmission line, substation and loop line would not occur, the No Transmission Line Alternative would have no direct or indirect effects on wetlands or streams.

3.23.4.6 Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

A total of 3.6 acres of wetlands and 4,822 linear feet of streams would be within the Alternative B transmission line clearing area (Table 186). Less than 0.1 acre of wetlands and 289 linear feet of streams would be affected by new or upgraded road construction. The need for culverts or other crossing types at streams would be determined during final design. Indirect effects on wetlands from road construction would be minimized by use of drive-through dips, open-top box culverts, waterbars or crossdrains, and implementation of BMPs. After an alignment was selected and the final wetland surveys were completed, any wetlands affected by the transmission line and access roads may be subject to conditions of the 318 authorization, and, where significant impacts occur, MFSA certification requirements if not covered by other mitigations. MMC would follow its proposed Environmental Specifications (MMI 2005b) and use BMPs during construction to minimize impacts. The BPA would avoid all wetlands at the Sedlak Park Substation Site.

Table 186. Wetlands and Streams within Clearing Area of the Transmission Line Alternatives.

Project Component	Alternative B – North Miller Creek	Alternative C-R – Modified North Miller Creek	Alternative D-R – Miller Creek	Alternative E-R – West Fisher Creek
Area of Jurisdictional Wetlands (acres)†				
Transmission Line Clearing	3.6	2.0	2.0	2.0
New or Upgraded Roads	0.1	0.1	0.1	0.1
Total Area	3.7	2.1	2.1	2.1
Area of Isolated Wetlands (acres)				
Transmission Line Clearing	<0.1	0.0	0.0	0.0
New or Upgraded Roads	0.0	0.0	0.0	0.0
Total Area	<0.1	0.0	0.0	0.0
Stream Length (linear feet)				
Transmission Line Clearing	4,822	1,922	2,935	3,380
New or Upgraded Roads	289	0	0	0
Total Linear Feet	5,111	1,922	2,935	3,380

The jurisdictional status of the wetlands and streams is preliminary and impacts may change during the 404 permitting process.
Units for areas are rounded to the nearest 0.1 acre; units for stream length are rounded to the nearest whole number
†Acreage is based on a 150-foot clearing width for monopoles (Alternative B) and 200-foot width for H-frame structures (all other alternatives except for a short segment of the West Fisher Creek Alternative E-R that has monopoles). Actual acreage cleared would be less than listed and would depend on tree height, slope, and line clearance above the ground.
Source: GIS analysis by ERO Resources Corp. using MMC data.

3.23.4.7 Alternative C-R – Modified North Miller Creek Transmission Line Alternative

A total of 2.0 acres of wetlands and 1,922 linear feet of streams would be within the clearing area of Alternative C-R (Table 186). The amount of wetlands in the clearing area of Alternative C-R is the same as Alternatives D-R and E-R; Alternative C-R would have the least effect on streams compared to the other alignments. Indirect and direct effects on wetlands and streams would be avoided where practicable during structure placement. Less than 0.1 acre of wetlands would be affected by new or upgraded road construction. Indirect effects would be minimized through BMPs and appropriate stream crossings, described in the agencies' Environmental Specifications (Appendix D).

3.23.4.8 Alternative D-R – Miller Creek Transmission Line Alternative

A total of 2.0 acres of wetlands and 2,935 linear feet of streams would be within the clearing area of Alternative D-R (Table 186). No wetlands or streams would be affected by new or upgraded road construction. Indirect effects would be minimized through BMPs and appropriate stream crossings, described in the agencies' Environmental Specifications (Appendix D).

3.23.4.9 Alternative E-R – West Fisher Creek Transmission Line Alternative

A total of 2.0 acres of wetlands, and 3,380 linear feet of streams would be within the clearing area of Alternative E-R (Table 186). No wetlands or streams would be affected by new or upgraded road construction. Indirect effects would be minimized through BMPs and appropriate stream crossings, described in the agencies' Environmental Specifications (Appendix D).

3.23.4.10 Proposed Mitigation and Monitoring Plans

A variety of measures would be used to avoid, minimize, or mitigate wetland effects during construction and operation. These measures would include BMPs, such as silt fence, revegetation of disturbed areas, and restoration of temporary wetland effects. Transmission line structures would be placed to avoid wetlands.

The Corps would be responsible for developing final mitigation requirements for jurisdictional waters of the U.S. including wetlands, depending on the functions and services of the affected wetlands. MMC used the MDT functional units method, the Corps' acreage ratio method, the MDT and hydrogeomorphic functions/services assessment, and the Montana Stream Mitigation Procedure to evaluate the amount of compensation needed for direct effects on wetlands and other waters of U.S. (MMC 2014a). Projects that implement mitigation before project losses would have a lower mitigation requirement than projects that implement mitigation concurrently or after wetland losses have occurred. The Corps typically does not establish mitigation requirements for non-jurisdictional wetlands. The agencies require mitigation for non-jurisdictional wetlands in Alternatives 3 and 4.

Proposed mitigation is considered either on-site or off-site. According to the compensatory mitigation regulations, on-site means an area located on the same parcel of land as the impact site, or on a parcel of land contiguous to the impact site. Off-site means an area that is neither located on the same parcel of land as the impact site, nor on a parcel of land contiguous to the parcel containing the impact site. The Corps is responsible for determining if a mitigation site is considered on-site or off-site.

3.23.4.10.1 Alternative 2 – MMC's Proposed Mine

MMC wetland mitigation plan would involve on-site and off-site locations. MMC proposes to replace forested and herbaceous wetlands at a 2:1 ratio and herbaceous/shrub wetlands at a 1:1 ratio. Annual monitoring of mitigation sites would ensure mitigation sites were dominated by hydrophytic vegetation and had comparable functions and services to the affected wetlands although no forested wetlands are proposed to replace the affected forested wetlands. Vegetation, soils, and hydrology data would be collected annually until the Corps has determined that wetland mitigation success was achieved. On-site mitigation opportunities would involve wetland restoration and wetland creation. Opportunities for wetland mitigation include sites along Little Cherry Creek. A total of 8.8 acres of on-site mitigation is proposed for Alternative 2 (Table 187) (Figure 21). Off-site mitigation would occur outside the permit area boundary. A total of 35.8 acres of off-site mitigation is proposed mitigate for effects associated with Alternative 2 (Table 187). Acreages shown in Table 187 for Alternative 2 are those presented in MMC's Plan of Operations and Hard Rock Operating Permit Application, and do not include those at the Swamp Creek site that MMC could use if acquired by MMC. Most of the mitigation sites would be located in the Poorman Creek area.

NMC's 1993 404 permit included more detailed designs for the North Poorman, South Poorman, and Ramsey creek sites (Corps 1993). The Poorman Weather Station mitigation site was not included in NMC's 1993 404 permit and the feasibility of creating 14 acres that replaced the lost functions of the wetlands affected by Alternative 2 is uncertain.

In all alternatives, the Corps would develop final mitigation requirements for jurisdictional wetlands and other waters of the U.S. In 2008, the Corps and the EPA issued regulations (33 CFR 332 and 40 CFR 230 Subpart J) regarding compensatory mitigation requirements for losses of aquatic resources, such as wetlands. These regulations require in cases where appropriate functional or condition assessment methods or other suitable metrics are available, these methods should be used where practicable to determine how much compensatory mitigation is required. If a functional or condition assessment or other suitable metric is not used, a minimum one-to-one acreage or linear foot compensation ratio must be used. Before issuance of the 2008 regulations, the Corps in Montana used ratios for various mitigation types in determining compensation requirements (Corps 2005). The Corps developed a stream mitigation procedure for projects adversely affected streams in 2010 and revised it in 2013 (Corps 2013a). MMC's plan is conceptual and would be refined during the 404 permitting process. MMC did not update its mitigation plan for Alternative 2 to reflect the new regulations and stream mitigation procedure.

Table 187. Jurisdictional Wetland Mitigation Opportunities by Alternative.

Mitigation Type and Site Name	Alternative 2 – MMC's Proposed Mine	Alternative 3 – Agency Mitigated Poorman Impoundment	Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment
On-Site			
Little Cherry Creek	2.2	0.0	0.0
Little Cherry Creek Diversion Channel	1.6	0.0	0.0
Unspecified Little Cherry Creek Site	5.0	0.0	0.0
Total On-Site	**8.8**	**0.0**	**0.0**
Off-Site			
North Poorman Creek	3.4	0.0	3.4
South Poorman Creek	9.7	0.0	9.7
Poorman Weather Station	14.0	0.0	14.0
Libby Creek Recreational Gold Panning Area	2.0	0.0	0.0
Ramsey Creek	6.7	0.0	6.7
Swamp Creek	0.0	15.0	15.0
Total Off-Site	**35.8**	**15.0**	**48.8**
Total Mitigation	**44.6**	**15.0**	**48.8**

All units are rounded to the nearest 0.1 acre.
Wetlands mitigation sites are shown for Alternative 2 on Figure 21 and for Alternatives 3 and 4 on Figure 33 and Figure 34.
The Corps is responsible for determining if a mitigation site is considered on-site or off-site.
Source: GIS analysis by ERO Resources Corp. using MMC data.

3.23.4.10.2 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

The agencies' Wetland Mitigation Plan for Alternative 3 is described in section 2.5.7.1, *Jurisdictional Wetlands and Other Waters of the U.S.*. MMC would implement the following mitigation as part of the wetland mitigation for 9.2 acres of direct effects and 0.2 acre of indirect effects (downgradient of the disturbance boundary) on wetlands from Alternative 3 (MMC 2014a):

- Rehabilitate 15 acres of wetland at the Swamp Creek site (Figure 34)
- Preserve 3 acres of upland vegetated buffer at the Swamp Creek site

MMC would implement the following stream mitigation (MMC 2014a):

- Reconstruct three existing channels at the Swamp Creek site to add meanders and to raise the channel bottom, adding 6,500 linear feet of stream
- Replace a culvert on Little Cherry Creek with a bottomless, arched culvert
- Replace a culvert on Poorman Creek with a bottomless arched culvert
- Stabilize 400 feet of erosion on NFS road #6212
- Remove a bridge across Poorman Creek and re-establish floodplain

- Remove 21 culverts and restore adjacent riparian habitat on lands acquired for grizzly bear mitigation

The Corps will determine the final mitigation requirements with the objective of replacing lost functions and services of the affected wetlands. The Corps will determine if the mitigation sites would be sufficient to meet the mitigation requirements for 9.2 acres of direct effects and 0.2 acre of indirect effect on jurisdictional wetlands, and the KNF will make the same determination for non-jurisdictional wetlands. MMC would submit more detailed plans for the selected jurisdictional mitigation sites for final approval by the Corps. Similar more detailed plans would be submitted to the KNF for isolated wetland mitigation sites.

The following sections briefly describe the wetland and stream mitigation proposed for Alternative 3, the basis for the anticipated hydrologic support for the mitigation site, the anticipated improvement in function and services that would be provided by the mitigation sites, and the anticipated credits associated with each site. A longer description of the proposed mitigation is found in section 2.5.7.1, *Jurisdictional Wetlands and Other Waters of the U.S.* in Chapter 2, with a full description provided in MMC's revised Mitigation Design Report (MMC 2014a). The anticipated improvement in function and services is based on MMC's revised Mitigation Design Report (MMC 2014a). The Corps is responsible for determining the amount of required compensatory mitigation necessary to replace lost jurisdictional wetland and stream functions and services. The Corps will determine compliance of the proposed discharges of fill with the 404(b)(1) Guidelines. The Corps will discuss compliance with the 404(b)(1) Guidelines in its ROD or Statement of Findings on the Section 404 permit. The Corps' findings regarding the least environmentally damaging practicable alternative and compliance with the 404(b)(1) Guidelines are subject to EPA's review.

Jurisdictional Wetland Mitigation

Swamp Creek Site

The Swamp Creek site is about 4 miles east of the Montanore Project site near US 2. Swamp Creek is a potential off-site wetland mitigation site where MMC has conducted hydrologic monitoring. In August 2011, MMC installed four piezometers at the site at depths that ranged from 5 to about 9 feet below ground surface. MMC collected data twice in 2011 and four times in 2012 and 2013 (NewFields Companies and Kline Environmental Research 2014). During the growing season, groundwater levels at one piezometer within the middle of the existing wetland ranged from 0.7 feet in August 2011 to 2 feet below the ground surface in September 2012. Groundwater levels at two piezometers on the west side of the exiting wetland were greater than 2 feet below the ground surface from August to September. Early growing season (May and June) measurements of groundwater were not taken at any of the piezometers and groundwater levels are not known.

About 15 acres of wetland would be rehabilitated at the Swamp Creek site. Three acres would become woody riparian habitat and 3 acres would be preserved for an vegetated upland buffer. The site is currently a wetland, and the rehabilitation has a high likelihood of success because the supportive hydrology is present.

The site has high cover of reed canarygrass, which can form dense stands and out compete other species. MMC plans to burn the grass, followed by plowing the soil and seeding the area with wetland vegetation. The performance standards developed by MMC for Alternatives 3 and 4 include having 30 percent cover or less of reed canarygrass (see section C.4 in Appendix C). Reed canarygrass is difficult to control because it has vigorous, rapidly spreading rhizomes and forms a large seed bank. Control of reed canarygrass is most effective when it includes an integrated approach implemented in a sequential and timely order. Ongoing maintenance to control sprouting and seedling establishment may be necessary to maintain long-term reed canarygrass control (Waggy 2010). If mitigation efforts created soils conditions that were more frequently saturated or inundated, the ecological conditions would be more favorable for species with higher moisture tolerances such as sedges and bulrushes.

The Swamp Creek mitigation site would increase the capacity for the area to perform all 15 functions and three services, in comparison to existing conditions at the Swamp Creek site. In addition, the Swamp Creek site would have similar functions and services as the affected wetlands. All but three of the functions would have high ratings at the rehabilitating wetland site, and all three services would also have high ratings (MMC 2014a). Mitigation credit would accrue from rehabilitating 15 acres of wetlands at a 1.5:1 ratio and protecting an upland buffer zone of 3 acres around the new wetland areas at a 5:1 ratio. MMC estimates total credits would be 10.6 acres.

Stream Mitigation

Swamp Creek Site

Stream mitigation at the Swamp Creek site would consist of constructing about 6,500 linear feet of new meandering channels, planting a 10-foot wide riparian zone on each side of the channels totaling about 3 acres, and removal of cattle on the property to prevent grazing along the channels. Three primary drainage channels located on the Swamp Creek site would be subject to channel restoration: main Swamp Creek channel and two tributary channels from Spring #2 and Spring #3.

Proposed mitigation would have direct benefits to the functions and services of the stream reaches on the Swamp Creek mitigation site, with benefits that would extend downstream in Swamp Creek and into Libby Creek. The Swamp Creek stream mitigation sites would raise the functions from low and medium ratings to mostly high ratings. All services at the Swamp Creek site currently have a low rating, but would be increased to mostly high ratings due to the planned future public access to the site (MMC 2014a). Mitigation credit would accrue from constructing about 6,500 linear feet of new meandering channels, improving 580 feet of existing channel (Spring #1), planting a 10-foot wide riparian zone on each side of the channels totaling about 3 acres, and restricting cattle from grazing along the stream channels.

Little Cherry Creek Site

Stream mitigation at the Little Cherry Creek sites would consist of replacing a culvert on NFS road #6212 with an arched culvert, following Forest Service stream simulation techniques (USDA Forest Service 2008a). The culvert replacement would improve passage for aquatic, semi-aquatic, and terrestrial biota and increase recreational potential.

Poorman Creek Sites

Stream mitigation at the Poorman Creek sites would consist of replacing one culvert across the creek at NFS road #278, removing one bridge on a decommissioned NFS road #6212 and stabilizing 400 feet of eroding cut slope adjacent to NFS road #6212. The bridge on NFS road #6212 across Poorman Creek would be removed during construction. Replacement of the road

#278 culvert would improve passage for fish possibly up to the first natural barrier and improve passage for an indefinite distance for semi-aquatic biota, including amphibians and mammals that are associated with water. Removal of the NFS road #6212 bridge and creation of a floodplain, and restored stream and riparian habitat would add surface water storage capacity during flood conditions, which would include associated nutrient cycling and sediment retention in the reestablished floodplain. Aquatic and semi-aquatic habitat and biota would benefit from reduced sediment downstream of the removed NFS road #6212 bridge due to reduced inputs from the road crossing and stabilization of erosion along the road. Benefits of increased organic inputs, nutrient cycling, fish production, and flood and erosion protection from the restored floodplain, and benefits of reduced sediment inputs would extend into Libby Creek (MMC 2014a). This reach would also be more appealing for recreation.

Lands Acquired for Grizzly Bear Mitigation

MMC would convey the title to or a perpetual conservation easement on 5,387 acres of land to the Forest Service or private conservation organization independent of MMC for grizzly bear mitigation. All lands would be acquired before the start of the Construction Phase. The Forest Service would ensure that the specified acres of mitigation properties were managed for grizzly bear habitat in perpetuity. The grizzly bear mitigation plan also would require MMC to implement access management improvements, such as road decommissioning and culvert removal, on mitigation lands. MMC would conduct a survey to assess all mitigation lands for opportunities to improve aquatic resources. Some of the types of activities that would be conducted to mitigate streams include: culvert removal and floodplain restoration, restoration of disturbed riparian buffer areas by removing roads and revegetating, addition of woody debris to the floodplain, removal of riprap and bridge abutments below the ordinary high water mark, removal of berms and other impervious fill material, and installation of instream habitat features to increase the value to aquatic life. MMC would use the Corps' Montana Stream Mitigation Procedure and the Corps' compensatory mitigation regulations (33 CFR 332) in assessing mitigation opportunities. For the purposes of assessing stream mitigation credits, MMC identified 21 culverts that would be removed and adjacent riparian habitat would be restored on 908 linear feet of stream on potential wildlife mitigation lands (MMC 2014a). The culvert removal would improve passage for aquatic, semi-aquatic, and terrestrial biota and increase recreational potential.

Summary of MMC's Proposed Jurisdictional Mitigation and Associated Credits and Debits

MMC's estimated wetland credits would be 10.6 acres. In its revised Mitigation Design Report (MMC 2014a), MMC did not include all wetlands and streams outside of the disturbance area or streams indirectly affected below the impoundment in determining mitigation debits. Assuming all wetlands within the Alternative 3 disturbance boundary would be filled or otherwise indirectly affected by the project and that wetlands below the disturbance boundary would be indirectly affected, total impact would be 9.4 acres, which would consist of 9.2 acres of and 0.2 acre of indirectly-affected jurisdictional wetlands downgradient of the disturbance boundary. MMC did not apply for a 404 permit to fill all jurisdictional wetlands within the disturbance boundary. If jurisdictional wetlands within the disturbance boundary could not be avoided during final design, MMC would have to modify its 404 permit, if issued for the project. Mitigation for isolated wetlands is described in the next section. While MMC has demonstrated that adequate jurisdictional wetland mitigation credits are available for debits determined by MMC, final jurisdictional wetland debits and credits will be determined by the Corps during the 404 permitting process.

Total direct and indirect steam impacts associated with construction of the impoundment would be 19,058 linear feet, which includes 13,272 linear feet direct effect within the disturbance boundary, 1,059 linear feet of direct effect from roads, and 4,727 linear feet of indirect effect below the disturbance boundary to Libby Creek. The effects on streams may be reduced during final design through avoidance and minimization efforts. While MMC has demonstrated that adequate stream mitigation credits are available for debits determined by MMC, the Corps would determine if the mitigation proposed by MMC for Alternative 3 would be adequate to offset unavoidable impacts to waters of the U. S. during the 404 permitting process. The above sections describe some of the possible opportunities to meet the required mitigation credits.

Isolated Wetland Mitigation

Little Cherry Creek Sites LCM-1, LCM-2, and LCM-3

As part of the planning process, MMC identified six potential mitigation sites adjacent to wetlands in the Little Cherry Creek Impoundment area. From 2010 to 2012, a total of eleven piezometers were installed at the six potential wetland mitigation sites at depths ranging from 3.2 to 5.1 feet. Depth to groundwater in the piezometers was measured once in 2010 and four times in 2011, 2012, and 2013, although often depth to groundwater was greater than the well depth (NewFields Companies and Kline Environmental Research 2014). Based on groundwater data, MMC identified Little Cherry Creek Mitigation Sites LCM-1, LCM-2, and LCM-3 with a combined total of 4.5 acres to meet a portion of its mitigation requirements. Groundwater levels measured in the piezometers show the water table is typically less than 2 feet below the ground surface in the spring and early summer and then declines until late summer.

Numerous small depressions would be excavated and lined with low permeability soil at the Little Cherry Creek sites LCM-1, LCM-2, and LCM-3 to create areas with palustrine emergent wetlands and seasonal open water areas. Surface water from snowmelt and direct rainfall would be the primary water source. If the title to or a perpetual conservation easement on Little Cherry Creek mitigation sites had not already been conveyed as part of the grizzly bear mitigation plan, MMC would convey the title to or a perpetual conservation easement on the Little Cherry Creek mitigation sites to the Forest Service after the Forest Service has determined the sites' performance standards had been met. Conveyed lands would be the isolated wetland mitigation sites, upland buffers, and adjacent existing wetlands contiguous to National Forest System lands. If a perpetual conservation easement was conveyed, the easement would allow for public access to the property. The proposed Little Cherry Creek wetland mitigation sites would improve the capacity of the area to perform all 15 functions and three services, in comparison to the existing upland conditions. The new wetlands generally would have similar or improved functions and services as the affected wetlands. Two of the functions (short- and long-term surface water storage; general wildlife habitat) would have high ratings for the new wetland sites, while all of the other functions and services except general fish habitat would have a medium rating (MMC 2014a). Mitigation credit would accrue from creating 4.5 acres of wetlands in uplands near the existing wetlands at a 2:1 ratio, and protecting an upland buffer zone of 2.5 acres around the new wetland areas at a 5:1 ratio. The agencies estimate credits would be 2.75 acres (Table 188).

Gravel Pit Site

The proposed Gravel Pit mitigation site was previously disturbed by gravel mining and remains unvegetated. In 2011, one piezometer was installed at the proposed Gravel Pit wetland mitigation site to a depth of 8.5 feet. Three monthly measurements were collected in 2011 and four monthly measurements were collected in 2012. During the growing season, groundwater levels ranged from 1.6 feet below ground surface in June 2012 to about 8 feet below ground surface in September 2011 (NewFields Companies and Kline Environmental Research 2014). Because the depth to groundwater would require extensive excavation, this mitigation site would be designed for precipitation as the supportive hydrology. Several small depressions would be excavated and lined with low permeability wetland soil to collect and hold precipitation, providing seasonal supportive hydrology. The success of this mitigation site would depend on proper construction and placement of the low permeability soil and adequate annual precipitation. Typically, groundwater-supported mitigation wetlands have a greater chance of success.

The Gravel Pit mitigation site would improve the capacity of the area to perform all 15 functions and three services, in comparison to existing conditions at the gravel pit. In addition, the new wetland site would have similar functions and services as the affected wetlands. Three of the functions (short- and long-term surface water storage; general wildlife habitat; and uniqueness) would have high ratings for the new wetland site, while all of the other functions and services except general fish habitat would have a medium rating (MMC 2014a). Mitigation credit would accrue from creating 3 acres of wetlands at a 2:1 ratio and protecting an upland buffer zone of 2 acres around the new wetland areas at a 5:1 ratio. The agencies estimate total credits would be 1.9 acres (Table 188).

MMC would convey the title or a perpetual conservation easement to the Forest Service for the following lands: lands contiguous with existing wetlands, the isolated wetland mitigation sites and National Forest System lands owned by MMC along Little Cherry.

Table 188. Summary of Isolated Wetland Mitigation and the Agencies' Estimated Credits, Alternative 3.

Mitigation Location	Mitigation Type	Mitigation Areas or Estimated Credit
Wetlands		
Three sites (LCM-1, LCM-2, LCM-3) near Little Cherry Creek	Wetland creation of 4.5 acres	2.25 acres wetlands (2:1 ratio); 0.5 acre upland buffer (5:1 ratio)
Former Gravel Pit near Poorman Creek	Wetland creation of 3.0 acres	1.5 acres wetlands (2:1 ratio); 0.4 acre upland buffer (5:1 ratio)
Total	7.5 acres	4.65 acres

Source: Agencies' analysis.

Mitigation for Other Potential Indirect Effects

The agencies did not require MMC to identify mitigation for three potential indirect effects of the project: affecting the hydrologic support for wetlands north of the Poorman Impoundment Site by the pumpback well system, reducing the flow in Poorman and Little Cherry creeks by the pump-back well system, and affecting the hydrologic support for wetlands and other aquatic resources in the upper watersheds of the East Fork Rock Creek and the East Fork Bull River. The agencies' approach for assessing and monitoring these potential effects and developing appropriate mitigation based on monitoring is described in the following sections.

Indirect Effects of the Pumpback Wells. MMC used a 3D model to predict the effect of the pumpback wells on the impoundment site's hydrology. In Alternative 3, the model predicted that the drawdown from the wells would extend to Little Cherry Creek, potentially affecting wetlands between the Poorman Impoundment Site and Little Cherry Creek. Alternatives 2 and 4 would have similar potential to affect wetlands indirectly (Table 185). Potential effects on streamflow in Libby Creek, Little Cherry Creek, and Poorman Creek from the pumpback wells were discussed in section 3.11.4.4. Streamflow was predicted by the model to be reduced by 0.55 cfs in Libby Creek, 0.04 cfs in Little Cherry Creek, and 0.18 cfs in Poorman Creek.

Section 3.10.4.2 indicates operation of a pumpback well system may not affect groundwater levels, surface resources, or five of the springs south of Little Cherry Creek because of an apparent subsurface bedrock ridge that separates groundwater flow between the watershed of Little Cherry Creek from those of Drainages 5 and 10 in the Poorman Impoundment Site (Chen Northern 1989). Because geologic and hydrologic data from the area between the Little Cherry Creek and Poorman drainages are limited, they are not sufficient to eliminate the possibility of the pumpback well system adversely affecting surface resources, particularly groundwater-supported wetlands. Additional subsurface data, such as aquifer pumping tests, from this area would be collected during the final design process of the Poorman Impoundment (see section 2.5.2.5, *Final Design Process* in Chapter 2 and Appendix C). These data would be used to confirm the geophysical results and the MMC's hydrogeologic interpretation. The 3D model would be rerun to evaluate the site conditions with the new data.

Section C.10 of Appendix C also describes wetland monitoring before operations began. One year before mill operation started, MMC would measure water levels in the piezometers in wetlands LCC-35 and LCC-39 four times over the annual hydrograph. The purpose of the monitoring would be to assess the potential effects of the pumpback well system. Vegetation in these two wetlands also would be monitored, following the methods used for the GDE monitoring. The monitoring would continue through the Closure Phase as long as the pumpback well system operated or until agreed upon by the agencies that it was no longer necessary. Streamflow in Libby Creek, Little Cherry Creek, and Poorman Creek also would be monitored. Should the updated tailings impoundment 3D model indicate streamflow or aquatic resources may be adversely affected by groundwater pumping, MMC would develop appropriate mitigation for the adverse effect. Mitigation would be identified and implemented before the pumpback well system began operation. Monitoring data collected during operations also would be used to assess effect. Conceptual mitigation options include providing hydrology support from groundwater wells or surface water or creating new wetlands on either National Forest System lands or private land north of Little Cherry Creek.

Indirect Effects of Mine Dewatering. Similar to the assessment of the Poorman Impoundment Site's hydrology, the agencies used 2D and 3D models to evaluate the site hydrogeology and analyze potential impacts due to mining. Although the results of the two models were similar, the 3D model provides a more detailed analysis, by incorporating known or suspected fault behavior with respect to hydrology; more recent underground hydraulic testing results; a more comprehensive calibration process, and better simulation of vertical hydraulic characteristics of the geologic formations to be encountered during the mining process. The effect on streamflow was discussed in section 3.11.4, *Surface Water Hydrology*. Section 3.10.4.3.5, *Groundwater Model Uncertainty* discusses model uncertainty. There is uncertainty associated with the hydraulic properties of the bedrock and faults; predictions of mine inflows and impacts on water resources are sensitive to permeability of major fault zones. With the data currently available, the model results provide a potential range of mine dewatering and pumping (in the case of the tailings impoundment model) rates and streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using currently available data in the groundwater models. The mine 3D groundwater model would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see section C.10.4, *Evaluation Phase* in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease.

Section C.10 of Appendix C also describes GDE inventory and monitoring and streamflow monitoring of in the mine area. The inventory area may change if the 3D groundwater model used to assess effects was updated and predicted greater or lesser effects. An inventory would help identify and rank GDEs based on their importance in sustaining critical habitats or species. The inventory would be conducted in accordance with the most current version of the Forest Service's *Groundwater Dependent Ecosystems: Level II Inventory Field Guide* (USDA Forest Service 2012b). The inventory, which began in 2009, includes a vegetation survey to describe and document existing vegetation characteristics and establish a prevalence index used by the Corps to determine wetland vegetation (Corps 2008d). The prevalence index would be used to assess changes in vegetation composition and if a loss of wetland species was occurring. The monitoring would continue through the Closure Phase as long as mine dewatering occurred or until agreed upon by the agencies that it was no longer necessary. Should the updated mine area 3D model indicate aquatic resources may be adversely affected by mine dewatering, MMC would develop appropriate mitigation for the adverse effect. Mitigation would be identified and implemented before the mill began operation. Monitoring data collected during operations also would be used to assess effect. Conceptual mitigation options include mitigation on lands acquired for grizzly bear mitigation. Some of the types of activities that would be conducted for mitigation include: remove culverts and restore the floodplain, restore disturbed riparian buffer areas by removing roads and revegetating, add woody debris to the floodplain, remove riprap and bridge abutments below the ordinary high water mark, remove berms and other impervious fill material, and install instream habitat features to increase the value to aquatic life.

3.23.4.10.3 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

The agencies' Wetland Mitigation Plan for Alternative 4 is described in section 2.6.7.1, *Wetlands Mitigation*. Jurisdictional wetlands would be replaced at a ratio determined by the Corps while isolated wetlands would be replaced using the Corps' 2005 ratios. A total of 48.8 acres of off-site mitigation were identified for Alternative 4. If the KNF selected Alternative 4 in the ROD, MMC would develop a mitigation design report for unavoidable effects on jurisdictional waters of the U.S. MMC would implement the wetland rehabilitation and stream restoration at Swamp Creek, the culvert replacement and the bridge replacement on NFS road #278 at Poorman Creek, and culvert removal on lands acquired for grizzly bear mitigation. Other possible wetland mitigation sites may include the North Poorman Creek, South Poorman Creek, Poorman Weather Station and Ramsey Creek sites shown in Table 187 and Figure 33. Insufficient mitigation sites were identified to achieve the Corps' minimum ratios for effects on jurisdictional wetlands, and additional mitigation sites would be necessary if this alternative were permitted. MMC would implement the mitigation described for the Gravel Pit site in Alternative 3 for mitigation for isolated wetlands.

In Alternative 4, the diversion channel for Little Cherry Creek would be a geomorphic-type diversion that would incorporate habitat components. Several mitigation measures would be implemented along the channel to ensure that erosion and sedimentation resulting from heavy rainfall and from high flow events would be minimized. Wetland soil, sod, and shrubs would be excavated from existing wetlands before filling during construction, and placed in the wetland mitigation areas. Use of existing wetland soils in mitigation would improve mitigation success.

As proposed in Alternative 3, 1 year of groundwater monitoring at the mitigation sites would be implemented in Alternative 4. Only sites with adequate existing groundwater available to support wetlands would be used for mitigation.

NMC's 1993 404 permit included more detailed designs for the North Poorman, South Poorman, and Ramsey creek sites (Corps 1993). The Poorman Weather Station mitigation site was not included in NMC's 1993 404 permit and the feasibility of creating 14 acres that replaced the lost functions of the wetlands affected by Alternative 4 is uncertain. According to MMC, the Poorman Weather Station mitigation site (Figure 33) is not within an area of existing wetlands and has no well-defined drainage. Wetlands created at this site may not be jurisdictional if the site does not have a hydrologic connection to a jurisdictional water. The discussion found on page 115 regarding mitigation requirements and on-site and off-site mitigation also applies to Alternative 4. Insufficient mitigation sites were identified to achieve the Corps' minimum ratios, and additional mitigation sites would be necessary if this alternative were permitted.

The agencies' wetland monitoring plan for Alternative 4 is similar to Alternative 3. In Alternative 4, flow from springs SP-02, SP-10, S-12, SP-14, SP-15 and SP-29 (Figure 40) would be measured and sampled for selected water quality parameters. MMC would monitor three wetlands if not filled by project activities: LCC-24, LCC-25, and LCC-39 (Figure 40). MMC would use the procedures established for monitoring of wetland mitigation sites described in Alternative 3 to describe and document existing vegetation characteristics and a prevalence index. A prevalence index would be used to assess changes in vegetation composition. Samples from any standing water in these three wetlands would be collected and analyzed for selected water quality parameters. Sampling would be repeated in mid-summer every 2 years until tailings disposal ceased. The revised monitoring plan would better evaluate the functions and services of the mitigation sites and the effects on downstream springs and wetlands.

3.23.4.11 Cumulative Effects

Past actions in the analysis area, particularly road construction, has resulted in the placement of culverts and other fill material in streams and adjacent wetlands. Past actions after the passage of the Clean Water Act in 1977 were subject to Section 404 permitting and mitigation requirements. Cumulative direct and indirect effects on waters of the U.S. may result from other reasonably foreseeable actions in the analysis area such as other mining operations and road construction. All present and reasonably foreseeable future actions regulated under Section 404 of the Clean Water Act would be subject to Corps' permitting and mitigation requirements. Some activities that may result in future effects on waters of the U.S. are exempt from Corps review under Section 404(f), and other activities with minimal effects do not require notification to the Corps for authorization. With appropriate mitigation, cumulative direct wetland effects would be negligible. Vegetation management projects, such the Flower Creek Vegetation Management project and the Miller-West Fisher Vegetation Management project, would avoid direct effects on waters of the U.S. by maintaining a RHCA buffer around wetlands and other waters. Typically, proposed activities on National Forest Systems lands are designed to meet standards prescribed by INFS. These design features would prohibit timber harvest, including firewood cutting, in RHCAs, thus limiting effects on waters of the U.S. Any activities within the KNF that are not subject to Corps review and that contribute to cumulative effects on waters of the U.S. would be mitigated under

Executive Order 11990. Wetland effects from KNF-approved access projects were not identified, and it would be the responsibility of the landowner to comply with the Clean Water Act. Cumulative indirect effects from reasonably foreseeable future actions in the area may include small amounts of increased sedimentation in wetlands from new roads associated with construction and ground-disturbing activities such as Miller-West Fisher Vegetation Management Project, and projects on private land such as housing development, roads, and logging.

3.23.4.12 Regulatory/Forest Plan Consistency

All of the action alternatives would involve the discharge of fill material or excavation into wetlands or waters of the U.S. MMC would apply for a permit and be required to follow conditions in the Section 404 permit. Plans for avoidance, minimization, and mitigation of effects on wetlands would be required before permit issuance. The agencies prepared a 404(b)(1) analysis that discusses compliance with the 404(b)(1) Guidelines (Appendix L). The lead agencies identified the Poorman Impoundment Site as the least environmentally damaging alternative for surface tailings disposal because it would have the least impacts on wetlands and waters of the U.S., and would not have other significant adverse environmental consequences (40 CFR 230.10(a)). As the permitting authority, the Corps will determine if mine Alternative 3 and transmission line Alternative D-R are the least environmentally damaging practicable alternatives. The Corps also will determine if the proposed project complies with the 404(b)(1) Guidelines. The Corps will discuss compliance with the 404(b)(1) Guidelines in its ROD or Statement of Findings on the Section 404 permit. The Corps' findings regarding the least environmentally damaging practicable alternative and compliance with the 404(b)(1) Guidelines are subject to EPA's review. Any alternative permitted by the Corps would comply with the KFP and Section 404 of the Clean Water Act.

In compliance with Executive Order 11990, the KNF finds that there is no practicable alternative to new construction located in wetlands, and that Alternative 3 would include all practicable measures to minimize harm to wetlands. Section 2.5.2.5.3, *Final Tailings Impoundment Design Process,* describes the agencies' requirements for the impoundment design before construction would begin. One mitigation measure would require MMC to avoid or minimize, to the extent practicable, filling wetlands and streams, such as described in Glasgow Engineering Group, Inc. (2010). This mitigation would ensure adverse effects on National Forest System lands would be minimized before considering compensatory mitigation and would comply with 36 CFR 228 Subpart A.

The Corps' wetland mitigation requirements would fulfill the Executive Order's requirements to minimize harm to jurisdictional wetlands. To minimize harm to isolated wetlands and comply with Executive Order 11990 and with 36 CFR 228 Subpart A regulations for locatable minerals operations on National Forest System lands, the KNF would require MMC to develop compensatory mitigation that would create 7.5 acres of wetlands and 4.5 acres of upland buffers. MMC would submit a final isolated wetland mitigation plan to the KNF for its approval and for incorporation into MMC's amended Plan of Operations.

3.23.4.13 Irreversible and Irretrievable Commitments

All action alternatives would result in an irretrievable commitment of wetlands and streams Successful mitigation would restore lost wetlands and provide similar functions and services to altered wetlands at another location. All action alternatives would affect wetlands and create changes in wetland functions and services. Some biodiversity in wetlands may ultimately be lost from invasion of introduced species and be irreversible under all action alternatives. Any differences in the function and services of the existing Little Cherry Creek channel and the proposed diversion channel in Alternatives 2 and 4 would be an irretrievable commitment.

3.23.4.14 Short-term Uses and Long-term Productivity

Potential short-term effects would result from time delays between the loss of existing wetlands resources and the development of the viable wetlands with similar functions and services. Proposed BMPs would minimize sedimentation. Other potential short-term effects would result from time delays between the loss of existing wetlands resources and the development of the viable wetlands with similar functions and services.

3.23.4.15 Unavoidable Adverse Environmental Effects

A loss of wetland functions and services, biodiversity, and species composition would occur in all action alternatives where wetlands are affected. The agencies anticipate effects on wetlands and streams would be mitigated and wetland functions and services would return to the area in time. The Corps would be responsible for establishing mitigation requirements for jurisdictional wetlands and other waters of the U.S. The KNF would be responsible for establishing and approving any wetland mitigation requirements for non-jurisdictional wetlands associated with the project on National Forest System lands. Any non-jurisdictional wetland affected by the transmission line and access roads may be subject to conditions of the 318 authorization, and, where significant impacts occur, MFSA certification requirements if not covered by other mitigations. The agencies' proposed mitigation would mitigate for direct effects on jurisdictional and isolated wetlands. Created wetlands biodiversity and species composition of forested wetlands would not return to pre-disturbance levels until decades after establishment. The diversity and species composition of herbaceous wetlands would likely be restored within 5 years.

3.24 Wilderness, Roadless Areas and Wild and Scenic Rivers

3.24.1 Cabinet Mountains Wilderness

3.24.1.1 Regulatory Framework

The CMW became a unit of the National Forest Wilderness Preservation System with the passage of the Wilderness Act on September 3, 1964. The Wilderness Act applies to the 94,272 acres of land within the CMW that were designated as part of the wilderness preservation system, not to activities and land outside the CMW boundary. The Wilderness Act directs the Forest Service to protect the natural character of the wilderness and to provide for recreational, scenic, scientific, educational, cultural, and historical uses of wilderness areas. Based on the Wilderness Act's definition of wilderness, the Forest Service uses four qualities to broadly describe all wilderness character in the National Forest System:

- Untrammeled – wilderness is essentially unhindered and free from modern human control or manipulation
- Undeveloped – wilderness is essentially without permanent improvements or modern human occupation
- Natural – wilderness ecological systems are substantially free from the effects of modern civilization
- Outstanding opportunities for solitude or a primitive and unconfined type of recreation – wilderness provides outstanding opportunities for people to experience solitude or primitive and unconfined recreation, including the values of inspiration and physical and mental challenge

More specific descriptions of these wilderness character qualities are described below under *Affected Environment*.

Section 4(d)(3) of the Wilderness Act pertains to mining claims within the wilderness and states that holders of unpatented mining claims validly established as of December 31, 1983 on National Forest System lands designated by the Act as a wilderness area will be accorded rights under the 1872 General Mining Law. The same section states that all patents issued on National Forest System lands designated as a wilderness area will convey only title to the mineral deposits within the claims and the United States reserves all title to the surface and surface resources of the claims. The Secretary of Agriculture may prescribe reasonable stipulations "for the protection of the wilderness character of the land consistent with the use of the land for the purposes for which they are leased, permitted, or licensed." The Secretary of Agriculture also may regulate ingress and egress consistent with the use of the land for mineral location and development. Consequently, mining operations can occur within the wilderness but may be subject to management requirements that are above and beyond those normally imposed on operations outside of a wilderness, provided those requirements do not prevent the operator from exercising due rights under United States mining laws. Forest Service mineral regulations (36 CFR 228, Subpart A) provide direction for administering locatable minerals operations on National Forest System lands. Specifically, 36 CFR 228.15 provides direction for operations within the National Forest Wilderness. Holders of validly existing mining claims within the National Forest

Wilderness are accorded the rights provided by the U.S. mining laws and must comply with the Forest Service mineral regulations (36 CFR 228, Subpart A). Mineral operations in the National Forest Wilderness are to be conducted to protect the surface resources in accordance with the general purpose of maintaining the wilderness unimpaired for future use and enjoyment as wilderness and to preserve the wilderness character consistent with the use of the land for mineral development and production.

The 1987 KFP allocated the CMW to MA 7. The goal of MA 7 is to manage it in accordance with the Wilderness Act, to allow natural processes to continue, maintain the opportunity for solitude and primitive recreation, provide habitat contributing to the recovery of the grizzly bear, and provide natural habitat for viable populations of other species of wildlife which have historically occupied the area. The standard for minerals and geology is that the valid existing rights recognized in the CMW will be managed in accordance with the Wilderness Act and other applicable laws and regulations.

In 2009, the KNF completed the Cabinet Mountains Wilderness Management Plan. The goal statement for the plan directs that the CMW "will be managed according to the Wilderness Act to allow natural processes to operate freely where the evidence of man's activity is substantially unnoticeable" (KNF 2009). Management direction in the plan is derived from the Wilderness Act and subsequent legislation which sought to protect these special areas and preserve wilderness character. The management plan identifies that valid existing rights for the Montanore ore deposit have been established in the CMW

3.24.1.2 Analysis Area and Methods

The analysis area encompasses the CMW south of the ridge separating Big Cherry Creek from Bear Creek (Figure 88). The CMW north of the ridge would not be affected, and, consequently, is outside of the analysis area. Potential effects on the CMW were qualitatively evaluated based on potential effects on wilderness attributes from the proposed project.

3.24.1.3 Affected Environment

The CMW is a 94,272-acre unit of the National Forest Wilderness Preservation System. It is about 34 miles long and varies from 0.5 to 7 miles wide (Figure 88). The wilderness occupies the upper elevations of the Cabinet Mountains, with elevations from 2,500 to 8,700 feet. The Cabinet Mountains are a north/northwest trending, extensively glaciated mountain range. This glaciation produced spectacular features such as high craggy peaks, vertical cliffs, knife-edge ridges, amphitheater-like basins, and filled valley bottoms. These land-building processes also have created many streams and about 85 lakes within the wilderness. MMC's mineral rights in the CMW are discussed in section 1.3.1, *Mineral Rights.*

3.24.1.3.1 Wilderness Character

The Forest Service's national framework for wilderness character was based on Section 2(c) of the Wilderness Act (Landres *et al*. 2008). These qualities of wilderness character provide the basis for the effects analysis.

- Untrammeled – The Wilderness Act states that wilderness is “an area where the earth and its community of life are untrammeled by man,” and “generally appears to have been affected primarily by the forces of nature.” Wilderness is essentially unhindered and free from modern human control or manipulation. This quality is degraded by modern human activities or actions that control or manipulate the components or processes of ecological systems inside the wilderness.
- Natural – The Wilderness Act states that wilderness is “protected and managed so as to preserve its natural conditions.” Wilderness ecological systems are substantially free from the effects of modern civilization. This quality is degraded by intended or unintended effects of modern people on the ecological systems inside the wilderness since the area was designated.
- Undeveloped – The Wilderness Act states that wilderness is “an area of undeveloped Federal land retaining its primeval character and influence, without permanent improvements or human habitation,” “where man himself is a visitor who does not remain” and “with the imprint of man’s work substantially unnoticeable.” This quality is degraded by the presence of structures, installations, habitations, and by the use of motor vehicles, motorized equipment, or mechanical transport that increases people’s ability to occupy or modify the environment.
- Solitude or a primitive and unconfined type of recreation – The Wilderness Act states that wilderness has “outstanding opportunities for solitude or a primitive and unconfined type of recreation.” This quality is about the opportunity for people to experience wilderness; it is not directly about visitor experiences per se. This quality is degraded by settings that reduce these opportunities, such as visitor encounters, signs of modern civilization, recreation facilities, and management restrictions on visitor behavior.

Untrammeled and natural are closely related, emphasizing natural ecological processes and an absence of modern disturbances. Both may be altered by the same activities. Undeveloped focuses on how the wilderness is perceived by the general public, while solitude or a primitive and unconfined type of recreation focuses on how visitors experience wilderness.

The CMW has a high degree of untrammeled, natural, and undeveloped qualities. Vegetation in the CMW is abundant and varied, ranging from delicate harebells growing in rock fissures to the lush, valley bottom stands of old growth cedar and hemlock. Thirteen species of conifer trees, 130 species of wildflowers, and numerous shrub species are known to grow in the wilderness. Many wildlife species inhabit the area within and adjacent to the wilderness. These include the grizzly bear, black bear, elk, bighorn sheep, mountain goats, lynx, mule deer, white-tailed deer, and various small mammals and birds.

Primitive recreation provides opportunities for isolation from the evidence of man. Visitors may enjoy a high degree of challenge and risk, and use of outdoor skills. The CMW offers opportunities for primitive recreational activities in a pristine setting. Hiking is the most popular activity in the wilderness. Fishing, photography, and hunting are the next most common activities pursued by wilderness visitors. The wilderness is split between Sanders and Lincoln counties. Access from the Lincoln County side is provided by 12 trails that are maintained on 1- to 2-year intervals and 19 trails are maintained on 3- to 4-year intervals. Access from the Sanders County side is provided by nine maintained trails and six trails not regularly maintained.

Solitude is isolation from sights, sounds, and the presence of others. The developments and evidence of man do not appear. Features that contribute to solitude include size of area and distance from perimeter to center. Vegetation and topographic screening are also related to solitude. The narrow configuration of the CMW (less than a mile wide at its narrowest point) has caused some pressures to occur at some of the more popular destination sites. The relatively easy access has also resulted in some sites receiving heavy use and visitor impacts.

3.24.1.3.2 Management

Management of the portion of the CMW in the analysis area is shared by two Ranger Districts of the KNF. To determine the type and extent of management actions appropriate for different portions of the wilderness, the Forest Service has identified two distinct opportunity classes for wilderness. The opportunity classes are delineated according to the biological, social, and managerial setting within the wilderness.

Opportunity Class I includes pristine areas without developed trails. The opportunity for solitude is high and one would not expect to see other groups or much evidence of recreation use. Dispersion of visitors is the management intention. Generally, no trails or other structures will be developed within the class. Existing travelways will be left in place and not maintained or marked. Existing facilities will be removed. Requests for research or other mineral development facilities will be evaluated on a case-by-case basis. Fish stocking does not currently occur and is not desirable in this area.

Opportunity Class II includes a delineation of trail corridors and more heavily used lake basins, such as Rock Lake and the trail along the East Fork Bull River to St. Paul Lake. Many lakes in this class are stocked with fish and have relatively easy access. These basins are very scenic, wildlife is often seen, and flowering plants are abundant. The lake basins and the trail corridors accessing them total less than 15 percent of the wilderness acres but account for most of the recreation use. Hiker use is steadily expanding in terms of geographical dispersion. Use has resulted in creation of new sites, expansion of camp areas, vegetation loss, tree damage, and human waste problems. To prevent resource impacts, recreation use should generally be concentrated in these areas.

General use of the CMW will not be promoted. Management activities that maintain or enhance the wilderness character, resource, solitude, or primitive and unconfined forms of recreation will be implemented (KNF 2009).

3.24.1.4 Environmental Consequences

3.24.1.4.1 Alternative 1 – No Mine

The CMW would not be directly affected by additional mine facilities. Sounds associated with existing activities at the Libby Adit Site would be audible within a small portion of the CMW in the upper Libby Creek drainage. Such activities on private land at the Libby Adit Site would remain until reclaimed in accordance with existing permits and approvals. Noise levels in the CMW would return to low, ambient levels when reclamation was completed.

3.24.1.4.2 Alternative 2 – MMC's Mine Proposal

All proposed surface disturbances associated with the mine facilities would occur outside the CMW boundary. None of the mine alternatives would physically disturb any lands within the

CMW directly and none of the four wilderness qualities would be directly affected. None of the alternatives would directly affect wilderness character.

The experience of wilderness visitors may be affected by mining-related activities occurring outside the CMW boundary. Because the wilderness experience is highly personal and individual, the perceived effect would differ among individuals. It is likely that the visual and noise effects of the project outside the CMW would reduce the natural quality of the wilderness experience for some individuals in portions of the wilderness. Visitation in the portions of the CMW exposed to sound and visual effects may decrease. Other qualities such as untrammeled, undeveloped, and outstanding opportunities for solitude or a primitive and unconfined type of recreation may also be diminished at some locations within the CMW for visitors while the project was in operation. These effects would occur throughout the duration of project operations and diminish following mining and reclamation. General indirect effects on wilderness character from Alternative 2 are described below.

Untrammeled

Effects on the untrammeled qualities of the CMW would stem primarily from effects on ecological systems, primarily wildlife and hydrology, within or adjacent to the wilderness. Short-term disturbances to wildlife in and adjacent to the CMW such as grizzly bear, mountain goat, and wolverine would occur from operation of the Ramsey Plant (see section 3.25, *Wildlife*). For all alternatives, blasting during construction of the adit openings would result in very short-term disturbances to wildlife in the CMW. Additional temporary disturbances to wildlife in the CMW would occur for Alternative 2 from helicopters used during construction of the transmission line to the Ramsey Plant Site. These impacts would be short term and would not impact the untrammeled quality of the CMW over the long term.

The CMW is part of a narrow, northwest trending corridor that provides the grizzly bear with a north-south movement corridor. The Cabinet Mountains are a rugged, glaciated mountain range of high relief. The topography of Cabinet Mountains and human development on the east and west sides constrict the width of effective grizzly bear habitat that is critical to grizzly bear movement between the southern Cabinet Mountains and the rest of the CYE (USFWS 2003a). The characteristics and importance of the north-south movement corridor are described in detail in the BA (USDA Forest Service 2013b). Long-term displacement effects from mine activities could inhibit grizzly bear movement in the north-south movement corridor in the Cabinet Mountains. Alternative 2 would have the greatest displacement effects in the north-south movement corridor, affecting 3,597 acres.

Direct effects on wildlife and habitat resources outside of CMW may have indirect effects on ecological processes within the CMW, due to long-term impacts on populations of wide-ranging species such as grizzly bear and wolverine. The extent to which the direct effect on wildlife and habitat outside of wilderness affects ecological processes within the CMW is uncertain; while some species may adapt to mine disturbance, others may avoid areas of mine activity and spend more time in the CMW (see *Wildlife* section 3.25).

Groundwater drawdown during all mine phases may indirectly impact aquatic habitat and associated ecological processes within the CMW. Changes in streamflow in Alternative 2 are discussed in section 3.10.4.2, *Alternative 2 – MMC Proposed Mine* in the *Groundwater Hydrology* section and section 3.11.4.3, *Alternative 2 – MMC Proposed Mine* in the *Surface Water Hydrology* section. The 3D model predicted flow in the East Fork Bull River, the East Fork

Rock Creek, and Libby Creek would be reduced in all mine phases, reaching a maximum reduction of 0.40 cfs in the East Fork Bull River, 0.29 cfs in the East Fork Rock Creek, and 0.07 cfs in Libby Creek at the CMW boundary during the Post-Closure Phase (Table 100). A permanent decrease of 0.01 cfs in the East Fork Bull River and 0.03 in the East Fork Rock Creek is predicted at the CMW boundary. At steady state conditions, streamflow in Libby Creek at the CMW boundary is predicted to return to pre-mine conditions Table 102.

Aquatic habitat for bull trout and other salmonids would be adversely affected. Low flows in the East Fork Bull River at the CMW boundary are estimated to decrease by 4 percent and 11 percent during the Closure Phase and Post-Closure Phases, respectively, without mitigation. Decreases in bull trout habitat availability would be similar for the reach near the Isabella Creek confluence and the reach near the CMW boundary with decreases of 4 to 5 percent predicted in both reaches for adult and juvenile bull trout habitat and 11 percent in spawning habitat (Table 76). Available habitat in the East Fork Bull River would essentially return to pre-mine conditions when the mine void filled and the potentiometric surface reached steady state conditions (Table 113), with a 1 percent or less predicted reduction in low flow. Macroinvertebrate populations are present throughout the reaches potentially affect by mine dewatering, and would be affected by the reduction or elimination of flow that would occur during low flow periods. Headwater streams also perform important ecological functions in terms of transport of organic matter, invertebrates, nutrients, and woody debris to downstream waters (Kline Environmental Research and NewFields 2012). Reductions in flow could adversely impact the ability of these headwater reaches to perform such functions. Effects on aquatic life are discussed in section 3.6.4, *Aquatic Life and Fisheries.*

In Alternative 2, the project would reduce the level and volume of Rock Lake during periods in which bedrock groundwater is the only source of supply to Rock Lake (Table 114). Reductions in lake levels and volume would probably not have a detectable effect on the aquatic biota of Rock Lake. While the lake volume is projected to be decreased by 2 percent post closure with mitigation and up to 5 percent without mitigation, aquatic habitat changes would likely be difficult to separate from those caused by natural variability in lake levels that occur in part due to large influxes of surface water into the lake during snowmelt and storm events (see *Aquatic Life and Fisheries*, section 3.6.4).

These direct and indirect impacts on ecological processes inside and adjacent to the wilderness, as described above, would not affect the untrammeled quality of the wilderness. The untrammeled quality would continue to appear to have been affected primarily by the forces of nature.

Natural

In Alternative 2, maximum modeled nitrogen deposition rates from the mine were greater than the Federal Land Manager (FLM) deposition analysis thresholds at Upper Libby Lake, Lower Libby Lake and Rock Lake; maximum modeled sulfur deposition rates were less than the deposition analysis thresholds at Lower Libby Lake and Rock Lake and greater than the deposition thresholds at Upper Libby Lake (Table 56). Effects of nitrogen and sulfur deposition in Alternative 2 on CMW lakes are discussed in section 3.4.4.2.7, *Cabinet Mountain Wilderness Impact Assessment* in the air quality section.

The lead agencies' analysis concluded that chimney subsidence breaching the surface to form sinkholes is unlikely given the geotechnical setting (thickness of the overlying rock above the mine workings, and the strength of the overlying rock) and the mine plan proposed by MMC (see section 3.14.3.1, *Subsidence* and Agapito Associates, Inc. 2007b). Isolated roof failure and chimney subsidence to some height above the workings is likely, and could lead to increased rock fracturing and higher groundwater hydraulic conductivity within the overlying strata. The evaluation also estimated that chimney subsidence impacts on groundwater may occur up to about 400 feet above the mine workings. The agencies' evaluation concluded that trough subsidence, while not likely, cannot be entirely dismissed at the current level of design. Without the agencies' mitigation described in section 2.5.2.5., *Final Design Process* and the agencies' monitoring described in Appendix C, Alternative 2 would have greater risks associated with subsidence than Alternatives 3 and 4.

Undeveloped

Under Alternative 2, mine construction or operation activities would not affect the undeveloped quality of the CMW because these activities are not proposed within the CMW. The undeveloped quality would not be affected because the wilderness would remain essentially without permanent improvements or modern human occupation.

Solitude or a Primitive and Unconfined Type of Recreation

Solitude within the CMW may be affected by the increased visibility of mine disturbances outside of the wilderness, as well as increased noise from mining facilities. Portions of the Montanore Project would be visible from at least one key viewpoint within the CMW at Elephant Peak. The Libby Adit Site, the Ramsey Plant Site, and the Little Cherry Creek Tailings Impoundment would potentially be visible from the CMW locations west of the facilities. The surface features of proposed Rock Lake Ventilation Adit, located adjacent to Rock Lake on a small parcel of private land outside the CMW would be minimal, but may be visible from some areas within the CMW. Night lighting of the mine facilities would be visible from portions of the CMW west of the facilities. Areas cleared of timber for mine facilities would be visible from some locations within the CMW. The visual effects of mining operations would be noticeable during construction and operations and would diminish following facility reclamation and closure.

Noise from mining facilities would be higher than existing levels in the CMW, potentially reducing solitude. During construction, operations, and reclamation, noise from generators, fans, equipment, traffic, and plant operations would extend westward into the CMW, with noise levels of 55 dBA at the CMW boundary diminishing to 30 dBA along the ridge between Elephant Peak and Bald Eagle Peak. Noise level associated with the Rock Lake Ventilation Adit is unlikely to be audible over ambient noise levels. Following mine closure and reclamation, noise levels and solitude in this portion of the CMW would return to pre-mine levels. Noise levels are discussed in section 3.20.4.

Alternative 2 would not affect opportunities for a primitive and unconfined type of recreation within the CMW. Any trails or access routes that are directly affected by mine facilities would be replaced with new routes and would not affect access to the wilderness. Increased access and familiarity with the area due to mine construction and operations and road improvements may increase recreational use within the wilderness. While increased use may diminish primitive recreation opportunities in some areas (particularly near the CMW boundary), it would not substantially affect the ability of some visitors to find high-quality opportunities for primitive recreation within the wilderness.

3.24.1.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Site

Impacts on the qualities of wilderness character and qualities would be similar to Alternative 2. Some mine facilities and roads would be visible from locations within the CMW. Noise levels in CMW would reach 30 dBA along the ridge between Elephant Peak and Ojibway Peak. Night lighting also would be visible from portions of the CMW. In Alternatives 3 and 4, MMC would shield or baffle night lighting at all facilities, minimizing effects on night sky.

Effects on visual quality and increased levels of noise would diminish wilderness qualities related to solitude from some locations in the CMW under Alternative 3. These effects would occur throughout the duration of project operations and diminish following mining and reclamation.

Untrammeled

Temporary disturbances to wildlife in the CMW would occur for Alternatives 3 and 4 from blasting during construction of the upper Libby Adit. MMC would not conduct any blasting at the entrance to any adit portals during May 15 to June 15 to avoid disturbance to the potential goat kidding area on Shaw Mountain.

Displacement effects on the grizzly bear in the north-south movement corridor would be comparable for the agencies' alternatives, with displacement effects in the north-south movement corridor about 1,700 acres less than Alternative 2. In the agencies' alternatives, long-term displacement effects in the north-south movement corridor would be mitigated through protection of an equal amount of grizzly bear habitat in the north-south movement corridor, where possible. To mitigate for displacement effects due to evaluation adit activities, the first 500 acres acquired or put into conservation easement would be within the north-south corridor in BMUs 2, 5, and 6 (Table 30).

Changes in streamflow in Alternative 3 are discussed in section 3.10.4.3, *Agency Mitigated Poorman Impoundment Site* in the *Groundwater Hydrology* section and section 3.11.4.4, *Agency Mitigated Poorman Impoundment Site* in the *Surface Water Hydrology* section. Effects on flow of CMW streams would be less in Alternative 3 with MMC's modeled mitigation and the agencies' mitigation. In Alternatives 3 and 4, the agencies have required additional mitigation, such as increasing the buffer zones near Rock Lake and the Rock Lake Fault, which was not modeled, and leaving one or more barrier pillars inside the mine. The mitigation is designed to minimize effects on East Fork Rock Creek and East Fork Bull River streamflow and water quality. With MMC's modeled mitigation, the 3D model predicted flow in upper Libby Creek would be slightly reduced in all mine phases and in the East Fork Bull River, the East Fork Rock Creek, and other drainages in the Operations, Closure, and Post-Closure Phases.

With MMC's modeled mitigation, decreases in bull trout habitat availability would be similar to Alternative 2 for the reach near the Isabella Creek confluence and the reach near the CMW boundary with decreases of 4 to 5 percent predicted in both reaches for adult and juvenile bull trout habitat and 11 percent in spawning habitat (Table 76). In Libby Creek at the CMW boundary would be 8 to 10 percent for adult and juvenile bull trout habitat and 20 percent in spawning habitat. Bull trout habitat availability would return to pre-mine conditions at steady state conditions. Mitigation projects planned to offset the risk of the population declines estimated to occur from the project in the Kootenai and Lower Clark Fork Core areas are described in more detail in the BA (USDA Forest Service 2013a) and in section 2.5.7.3, *Bull Trout.*

With MMC's modeled mitigation, the 3D model predicted less of a reduction in the potentiometric surface at Rock Lake. During operations, the effect on Rock Lake would be slightly less with MMC's modeled mitigation than without (Table 114). The agencies' mitigation, leaving barrier pillars with access-opening bulkheads, would be designed, based on hydrologic data collected during mining, to minimize post-mining changes in East Fork Rock Creek and East Fork Bull River streamflow and water quality. The agencies' mitigation of increasing the buffer zones near Rock Lake and the Rock Lake Fault, may eliminate effects on Rock Lake during and after mining. Reductions in lake levels and volume would probably not have a detectable effect on the aquatic biota of Rock Lake.

These direct and indirect impacts on ecological processes inside and adjacent to the wilderness, as described above, would not affect the untrammeled quality of the wilderness. The untrammeled quality would continue to appear to have been affected primarily by the forces of nature.

Natural

Modeled maximum nitrogen deposition rates from the mine were less than the FLM deposition analysis threshold at Upper Libby Lake, Lower Libby Lake and Rock Lake (Table 61). Sulfur deposition rates are expected to be below the sulfur deposition analysis threshold (Klepfer Mining Services 2013a). The agencies' mitigation, such as limiting generator use at the mill after power was available from a transmission line to 16 hours during any rolling 12-month time period and using Tier 4 engines and ultra-low sulfur diesel fuel in underground mobile equipment, would substantially reduce emissions compared to Alternative 2. Nitrogen and sulfur emissions from the mine would substantially decrease when underground mining ceased and would end after the adits were plugged. Effects of nitrogen and sulfur deposition in Alternatives 3 and 4 on CMW lakes are discussed in section 3.4.4.3.3, *Cabinet Mountain Wilderness Impact Assessment*.

In Alternatives 3 and 4, MMC would monitor nitrogen and sulfur emissions at the Libby Adit for a minimum of 2 years. Using the monitoring data, MMC would update the nitrogen and sulfur deposition analysis and compare the updated model results to the current FLM deposition analysis thresholds. MMC would also assess potential effects on lake ANC if appropriate methods were available. If modeled results using the Libby Adit monitoring data were greater than current FLM deposition analysis thresholds, MMC would develop a plan for agencies' review that evaluated all available control technologies to reduce pollutant emissions.

Potential risk of subsidence would be less Alternative 2. The agencies' mitigation for subsidence, described in section 2.5.2.5.4, *Final Underground Mine Design Process*, the agencies' mitigation of increasing the buffer zones near Rock Lake and the Rock Lake Fault, and the agencies' monitoring, described in Appendix C, coupled with final design criteria submitted for the agencies' approval, would minimize the risk of subsidence and associated effects on surface resources in the CMW.

As part of the Alternative 3 grizzly bear mitigation plan, MMC would fund access changes on five roads leading providing access to the CMW in the Bear, Poorman, Ramsey, Libby, and Standard creek drainages. These roads would be barriered and converted into trails. These access changes would improve the manageability and boundaries of the Cabinet Face East IRA, Access on Rock Lake Trail #935, which currently access to Rock Lake and St. Paul Pass in the CMW, would change from being open to snow vehicles December 1 through April 30 to being restricted to all motorized vehicles, including over-snow vehicles. These access changes would improve the wilderness quality of natural. The opportunities for solitude or a primitive and unconfined type of recreation also would improve.

Solitude or a Primitive and Unconfined Type of Recreation

The agencies' proposed access changes would improve opportunities for solitude or a primitive and unconfined type of recreation. The agencies' proposed water resources monitoring would require monitoring of water resources in the East Fork Rock Creek, East Fork Bull River, and Swamp Creek drainages (see Appendix C). Increased use by project personnel conducting the monitoring would decrease opportunities for solitude or a primitive and unconfined type of recreation in the East Fork Rock Creek, East Fork Bull River, and Swamp Creek drainages.

Effectiveness of Agencies' Proposed Mitigation

The agencies mitigation would be effective in minimizing adverse effects on surface resources in the CMW, maintaining the wilderness unimpaired for future use and enjoyment as wilderness a and preserving the wilderness character consistent with the use of the land for mineral development and production in compliance with 36 CFR 228.15. Mitigation measures such as increasing the buffer zones near Rock Lake and the Rock Lake Fault, and the agencies' monitoring coupled with final design criteria submitted for the agencies' approval, would reduce the risk of subsidence and measurable hydrological indirect effects to the surface within the wilderness. In Alternative 3 and 4, potential air quality indirect impacts on wilderness lakes and wilderness character would be minimized by mitigation measures such as limiting generator use, and using tier 4 engines and low sulfur diesel fuel in underground mobile equipment by reducing emissions.

3.24.1.4.4 Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Site

Impacts on the qualities of wilderness character from the plant and adit sites and from the agencies' proposed mitigations and monitoring would be the same as Alternative 3; the impoundment would have the same effects as Alternative 2. Some mine facilities and roads would be visible from some viewpoints within the CMW. Noise levels would be similar to Alternative 3, and night lighting also would be visible from portions of the CMW. Effects on visual quality and increased levels of noise would diminish wilderness attributes related to solitude from some locations in the CMW under Alternative 4.

3.24.1.4.5 Alternative A – No Transmission Line

In Alternative A, the transmission line, substation, and loop line for the Montanore Project would not be built and CMW would not be affected.

3.24.1.4.6 Effects Common to Alternatives B, C-R, D-R and E-R

The alternative transmission lines alignments, substation, or loop line would not encroach on CMW. Views from within the CMW would be affected by a new transmission line, particularly from high, open vistas such as Elephant Peak within the CMW. None of the transmission line alternatives, substation, or loop line would affect wilderness character.

3.24.2 Roadless Areas

3.24.2.1 Regulatory Framework

The 1987 KFP identified 32 inventoried roadless areas (IRAs) on the KNF. In 1999, the inventory was updated and an additional 11 areas were identified as IRAs. These 43 IRAs on the KNF were included in the 2001 Roadless Area Conservation Rule.

IRAs are areas identified by the Forest Service for consideration of their suitability for inclusion in the National Wilderness Preservation System. IRAs are defined as "areas identified in a set of inventoried roadless area maps, contained in the Forest Service Roadless Area Conservation, Final Environmental Impact Statement, Volume 2, dated November 2000, and any subsequent update or revision of those maps through the land management planning process" (36 CFR 294.11). Capabilities of IRAs for wilderness suitability include primitive recreation opportunities or opportunities for solitude, natural integrity and appearance, manageability and boundaries, and special features (Land Management Planning Handbook, FSH 1909.12, chapter 70-Wilderness Evaluation). Roadless areas provide opportunities for restoration of ecosystem function and improvement of threatened, endangered, proposed, and sensitive species habitat (Tidwell 2012).

In 2001, the Forest Service promulgated the Roadless Area Conservation Rule (formerly 36 CFR 294, Subpart B), which established prohibitions of road construction and reconstruction and timber harvesting in IRAs on National Forest System lands, with certain exceptions. One of the exceptions was for locatable mining activities, such as the Montanore Project, for which reasonable access and disturbance for mineral entry within an IRA was allowed. The 2001 Roadless Rule was the subject of litigation in multiple jurisdictions. Ultimately, the rule was judicially upheld and it is in effect, with the exceptions of the States of Idaho and Colorado where separate rules apply. See Wyoming v. U.S.D.A., 661 F.3d 1209 (10th Cir. 2011) (upholding 2001 Roadless Rule); Kootenai Tribe of Idaho v. Veneman, 313 F.3d 1094 (9th Cir. 2002) (reinstating Roadless Rule); Jayne v. Sherman, No. 11-35269 (9th Cir. 2013) (upholding Idaho Roadless Rule). In 2012, the Chief of the Forest Service indicated that he would continue to review projects involving road construction or reconstruction and the cutting, sale, or removal of timber in IRAs, except for some projects he delegated to Regional Foresters (Tidwell 2012).

3.24.2.2 Analysis Area and Methods

The analysis area encompasses the Cabinet Face East IRA east of the CMW and south of the ridge between Big Cherry Creek and Bear Creek, the Rock Creek IRA on the west side of the CMW, and that portion of the McKay Creek IRA adjacent to the East Fork Rock Creek (Figure 88). Although other IRAs are shown on Figure 88, they would not be affected by any of the alternatives, and are not discussed further. The analysis of effects on IRAs was quantitatively based on direct effects within an IRA and qualitatively based on indirect effects on IRA capabilities. Data on the IRA capabilities were taken from the KFP Final EIS (USDA Forest Service 1987a).

3.24.2.3 Affected Environment

The Cabinet Face East IRA lies just east of the CMW and extends about 36 miles south from Libby (Figure 88). The entire IRA consists of 50,200 acres of National Forest System lands and 800 acres of private lands. The average width is about 2 miles. This IRA provides attributes and recreational opportunity similar to those found in the CMW. The McKay Creek IRA includes sidehill and ridgetop features and steep-sided stream bottoms. The Rock Creek IRA is a steep and rugged area that is surrounded by the CMW on three sides. Both the McKay and the Rock Creek IRAs are a destination for recreationists accessing the CMW from the Rock Creek drainage (USDA Forest Service 1987a). Under the 2005 roadless rule (36 CFR 294, Subpart B), management requirements for IRAs are guided by KFP. Most of the Cabinet Face East, McKay and Rock Creek IRAs are managed by the KNF under MA 2, Semi-primitive non-motorized recreation. Section 3.15.3.2.2, *Management Area Goals and Standards* discusses applicable KFP goals and standards of MA 2.

3.24.2.3.1 Inventoried Roadless Area Capabilities

The KNF (USDA Forest Service 1987a) identified the following characteristics of the IRAs in the analysis area that could make them suitable for wilderness recommendation.

Natural Integrity and Appearance

The Cabinet Face East IRA excludes most improvements and all roads, leaving it very natural appearing. Man-made features within the IRA include trails and evidence of historical mining activity. The McKay Creek IRA has high natural integrity with trails being the only man-made features. The natural integrity of the Rock Creek IRA is high with no man-made features to detract from the area's natural appearance.

Opportunities for Solitude

The Cabinet Face East IRA opportunity for solitude is low along trail systems and destinations due to the relatively high annual visitation in these areas. The Rock Creek and McKay Creek IRAs have high opportunities for solitude in the Rock Creek areas.

Primitive Recreation Opportunities

Primitive recreation opportunities available in the Cabinet Face East IRA include hiking, hunting, stream fishing, and horseback riding. Challenging experiences are available such as cross-country ski touring. Primitive recreation opportunities in the McKay Creek IRA include hunting, hiking and fishing. Opportunities in the Rock Creek IRA include hiking, viewing, and wildlife observation.

Roadless Area Manageability and Boundaries

Cabinet Face East IRA is a long, linear roadless area with boundaries easily defined in some places and less so in others. Less definable boundaries are due to the exclusion of some narrow drainage corridors in Bear, Cable, Poorman, Ramsey, and Libby Creeks where roads exist. The IRA spans the length of the CMW on its east side and provides a buffer zone to it, making the CMW more manageable for wilderness characteristics. The McKay Creek IRA boundary does not follow topographic features; otherwise the boundary enhances the CMW boundary by providing depth and solitude. The Rock Creek IRA is well-defined by a closed road (150A) and the CMW, making for an easily managed boundary.

Special Features

The Cabinet Face East IRA has many special features including grizzly bear, goat, and moose habitat and views of historical mining activity. Ramsey Lake, a very small lake surrounded by old growth, is also a special scenic feature within the analysis area. The lake receives very little recreational use. Special features within the McKay Creek IRA are wildlife observation and skiing into Rock Creek. The 1987 KFP did not identify any special features in the Rock Creek IRA.

3.24.2.3.2 Other Unroaded Areas

The analysis area contains several areas of unroaded National Forest System lands that are adjacent or contiguous to IRAs. Five tracts of unroaded lands were identified (ERO Resources Corp. 2010b), with two larger areas, adjacent to but separated by roads from an IRA: 1) a 3,500-acre area in the Miller Creek drainage, and 2) a 900-acre area west of the Bear Creek Road in the Upper Little Cherry Creek drainage. The other three areas are smaller (64 to 200 acres) tracts that are contiguous to an IRA between Libby and Poorman Creeks. Unroaded areas analyzed in this document are those with criteria such as proximity to existing Wilderness or IRAs, larger size, overlap with protective Management Area or Recreation Opportunity Spectrum designations, or wildlife habitat. The analysis included unroaded areas that are adjacent to but separated from an IRA by road systems and unroaded areas that are contiguous to an IRA.

3.24.2.4 Environmental Consequences

3.24.2.4.1 Inventoried Roadless Areas

Alternative 1 – No Mine

Alternative 1 would not directly affect the Cabinet Face East IRA. Sounds associated with the activities at the Libby Adit Site would be audible within portions of the Cabinet Face East IRA in the Libby Creek drainage. Noise levels in the IRA would return to low, ambient levels when closure and reclamation was completed at the site. Noise levels are discussed in section 3.20.4.

Alternative 2 – MMC's Mine Proposal

Mine facilities in Alternative 2 would directly affect about 44 acres, or about 0.1 percent, of the Cabinet Face East IRA in the Ramsey Creek drainage. Timber harvest in the IRA would occur at the Ramsey Plant Site and a portion of LAD Area 1, and a road to the Ramsey Adits and LAD Area 1 would be built in the IRA. The Libby Adit Site, the Ramsey Plant Site, and the Little Cherry Creek Tailings Impoundment also would be visible from portions of the IRA. Night lighting at some mine facilities would be visible from the IRA. Roads and clearing areas may be visible from locations with high or open vantage points. Visual effects would be noticeable during construction and operations, and diminish following facility reclamation and closure. The visual effects of Alternative 2 are discussed in section 3.17.4.

Sound levels between 30 and 45 dBAs would be audible for distances up to 1 mile from the eastern boundary of the IRA (Big Sky Acoustics 2006). The Cabinet Face East IRA boundary is segmented on the eastern edge by narrow corridors that exclude the roads in several drainages including Ramsey Creek (Figure 88). These narrow corridors will allow for some non-conforming uses adjacent to the IRA. The project would have no direct effect on Ramsey Lake, but would restrict access to it. The plant site would be located about 1,000 feet northeast of the lake. The noise level at Ramsey Lake would increase to about 55 dBA during construction and would be slightly lower during operations. Noise levels are discussed in section 3.20.4.

Natural Integrity and Appearance

Alternative 2 would not change the overall appearance of the Cabinet Face East IRA, but would affect the appearance of the IRA in locations nearest the direct impact. Changes in natural integrity and apparent naturalness would occur at the edges of the Cabinet Face East IRA in the

Ramsey Creek drainage by the Ramsey Plant site and LAD Area 1. Emissions from the mill and adits would increase concentrations of priority air pollutants in the IRA adjacent to Ramsey Creek; concentrations of all pollutants would be below applicable standards (Table 51). The increased concentrations would reduce the natural integrity of the IRA adjacent to Ramsey Creek. Effects on air quality are discussed in section 3.6.4, *Air Quality.* The indirect effect on baseflow described in section 3.24.1.4.2, *Alternative 2 – MMC's Mine Proposal* in the wilderness section would reduce the natural integrity of the Rock Creek and McKay Creek IRAs.

Opportunities for Solitude

Proposed facilities in Ramsey Creek and Little Cherry Creek drainages also would reduce the opportunity for solitude on the east side of the Cabinet Face East IRA from Libby Creek watershed north to Bear Creek watershed because of the increased sound levels that would be generated by mine operations. Following mine closure and reclamation, noise levels and opportunities for solitude in the IRA would return to pre-mine conditions. Alternative 2 would not affect the opportunities for solitude in the Rock Creek and McKay Creek IRAs.

Primitive Recreation Opportunities

Views of the Libby Adit Site, the Ramsey Plant Site, and the Little Cherry Creek Tailings Impoundment from high or open locations in the IRA may affect some visitors' primitive recreational experience. Alternative 2 would restrict access to portions of the Ramsey Creek drainage beyond LAD Area 1, eliminating recreational opportunities in those portions of the IRA. Access to Poorman Creek also would be restricted under Alternative 2. The access restriction would continue for the life of the project. Due to the restricted access and noise levels, visitors to the area also would likely no longer make Ramsey Lake a destination under this alternative during the project's life. Primitive recreation opportunities would not be affected in the rest of the roadless area. Primitive recreation opportunities would return to pre-mine levels after mine closure and reclamation. Alternative 2 would not affect the primitive recreational opportunities in the Rock Creek and McKay Creek IRAs.

Special Features

Access to Ramsey Lake would be restricted and noise levels would be high enough to deter visitation during the life of the project. Alternative 2 would not affect the special features of the Rock Creek and McKay Creek IRAs. The effects on the special feature of grizzly bear, goat, and moose habitat in the Cabinet Face East IRA are described in the section 3.25, *Wildlife.* None of the mine alternatives would affect views of historical mining activity.

Manageability and Boundaries

The Cabinet East Face IRA would be affected by the Ramsey Plant Site and LAD Area 1 in the Ramsey Creek drainage, which could prevent the expansion or establishment of a future CMW boundary in Ramsey Creek drainage. Manageability and boundaries would return to pre-mine conditions after mine closure and reclamation. Alternative 2 would not affect the manageability and boundaries of the Rock Creek or McKay Creek IRAs.

Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Cabinet Face East IRA

Alternative 3 would avoid all surface disturbance in the IRA. No road construction or timber harvest would occur in the IRA west of LAD Area 1 or at the Ramsey Plant Site. Increased noise levels from the Libby Plant Site would be audible from within the IRA between Libby and Ramsey creeks. Similar noise levels would be audible from within the IRA adjacent to the Libby Adit Site and Libby Plant Site. Adverse visual impacts from activities occurring outside the IRA would be similar to Alternative 2.

Alternative 3 would not change the overall appearance of the Cabinet Face East IRA, but would affect the appearance of the IRA in locations nearest the direct impact. Changes in natural integrity and apparent naturalness would occur at the edges of the Cabinet Face East IRA in the Libby Creek drainage by the Libby Plant Site and Libby adits. Opportunities for solitude and primitive recreation would be eliminated in the IRA near the Libby Plant Site and Libby adits.

Emissions from the mill and adits would increase concentrations of priority air pollutants in the IRA adjacent to Libby and Ramsey creeks; concentrations of all pollutants would be below applicable standards (Table 57 and Table 58). The increased concentrations would reduce the natural integrity of the IRA adjacent to Libby and Ramsey creeks. The agencies' mitigation, such as limiting generator use at the mill after power was available from a transmission line to 16 hours during any rolling 12-month time period and using Tier 4 engines and ultra-low sulfur diesel fuel in underground mobile equipment, would substantially reduce emissions compared to Alternative 2. Effects on air quality are discussed in section 3.4.4, *Air Quality.* IRA attributes would return to pre-mine conditions after mine closure and reclamation. IRA attributes would return to pre-mine conditions after mine closure and reclamation.

MMC would fund access changes on five roads leading into the Cabinet Face East IRA in the Bear, Poorman, Ramsey, Libby, and Standard creek drainages. These roads would be barriered and converted into trails. These access changes would improve the opportunities for solitude and primitive recreation as well as manageability and boundaries of the Cabinet Face East IRA.

Rock Creek and McKay IRAs

The indirect effect on baseflow described in section 3.24.1.4.2*, Alternative 2 – MMC's Mine Proposal* in the wilderness section and in section 3.10.4, *Groundwater* would reduce the natural integrity of the Rock Creek and McKay Creek IRAs. The agencies' mitigation of increasing the buffer zones near Rock Lake and the Rock Lake Fault which was not modeled, and leaving one or more barrier pillars inside the mine, is designed to minimize effects on East Fork Rock Creek streamflow.

The agencies' proposed water resources monitoring would require monitoring of water resources in the East Fork Rock Creek, East Fork Bull River, and Swamp Creek drainages (see Appendix C). Increased use by project personnel conducting the monitoring would decrease opportunities for solitude or a primitive and unconfined type of recreation in the East Fork Rock Creek, East Fork Bull River, and Swamp Creek drainages.

Access on Rock Lake Trail #935, which currently separates the Rock Creek IRA from the McKay IRA would change from being open to snow vehicles December 1 through April 30 to being restricted to all motorized vehicles, including over-snow vehicles. The change would improve the wintertime opportunities for solitude and primitive recreation. In addition, MMC would secure or protect through conservation easement, including motorized route access changes, or acquisition in fee with conveyance of fee or perpetual conservation easement to the Forest Service or private conservation organization independent of MMC from development (including but not limited to housing, motorized access) and use (timber harvest, grazing, and mining) about 5 acres of replacement habitat near Rock Creek Meadows between the Rock Creek IRA and the McKay IRA. Forest Service acquisition of this parcel, coupled with the access change on Rock Lake Trail #935 would improve the manageability and boundaries of the Rock Creek and McKay IRAs.

Effectiveness of Agencies' Proposed Mitigation

The agencies alternatives would not require road construction and timber harvest within an IRA.

Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

No road construction or timber harvest would occur in any IRA. Effects on the Cabinet Face East IRA would be similar to Alternative 3 due to similar positioning of the facilities in and near Libby Creek. Predicted changes to the Rock Creek and McKay Creek IRAs would be the same as Alternative 3.

Alternative A – No Transmission Line

In Alternative A, the transmission line, substation, and loop line for the Montanore Project would not be built and the Cabinet Face East IRA would not be affected.

Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

MMC's proposed North Miller Creek transmission line alignment would physically disturb about 2 acres of the Cabinet Face East IRA in the Ramsey Creek drainage. Timber harvest for line clearing would occur in the IRA. The small area disturbed in the IRA would not directly affect the primitive recreation opportunities and other features, opportunities for solitude, roadless area manageability and boundaries, or special features and special values. The steel monopoles, new roads and associated timber harvest, which would be required under Alternative B, would parallel the IRA boundary along most of Ramsey Creek, and would be visible from some viewpoints within the IRA, particularly high, open vistas. These views also may contribute to a loss of opportunities for solitude for some visitors to the IRA. Noise from transmission line construction would be audible in the IRA adjacent to Ramsey Creek. Noise levels are discussed in section 3.20.4. IRA attributes would return to pre-transmission line conditions after transmission line decommissioning. The substation and loop line would not affect the Cabinet Face East IRA in any alternative.

Effects Common to Alternatives C-R, D-R, and E-R

The other three transmission line alternatives would avoid physical disturbance in the IRAs. No road construction or timber harvest would occur in the IRAs. Transmission line construction to the Libby Plant Site would be audible in the Cabinet Face East IRA between Libby and Ramsey creeks. Views from the IRA would be affected by new H-frame transmission lines, particularly from high, open vistas. Cabinet Face East IRA attributes would return to pre-transmission line conditions after transmission line decommissioning. Attributes of the Rock Creek and McKay Creek IRAs would not be affected.

3.24.2.4.2 Other Unroaded Areas

Mine Alternatives

The mine facilities proposed in Alternatives 2, 3, and 4 would adversely affect an unroaded area, adjacent to but separated by roads from an IRA, in the upper Little Cherry Creek drainage by the various tailings impoundment and road configurations. While the impacts of the alternatives would be similar, Alternative 2 would have the greatest effect on this area by reducing the acres of unroaded area. These impacts would reduce the size of unroaded area (ERO Resources Corp. 2010b).

The impacts of the proposed mine alternatives on the other, smaller unroaded areas, contiguous to an IRA, between Libby Creek and Poorman Creek, would vary. Alternative 2 would have the greatest impact, fragmenting or eliminating two of these three areas while leaving the smallest (north of Libby Creek) intact. Alternatives 3 and 4 would eliminate the smallest area, but would not impact the other two, including the larger area north of Ramsey Creek. Overall, Alternative 2 would have the greatest impacts on unroaded areas, followed by Alternatives 4 and 3.

Transmission Line Alternatives

All of the transmission line alternatives would cross over the outer edge of the unroaded area in the Miller Creek drainage. Alternatives B and C-R would cross the northeastern edge of the unroaded area, Alternative D-R would cross along the southern edge, and Alternative E-R would cross small portions of the southwestern edge. Alternatives B and C-R would have the greatest impact, requiring vegetation clearing of 15,000 feet of centerline, further fragmenting the outer edge of this unroaded area, and reducing its overall size.

Alternative B would construct roads in the unroaded area (Figure 41), while use of helicopter for clearing in Alternative C-R would eliminate the need for road construction (Figure 44). Alternatives B and C-R would not impact the area's overall resource values and character. Alternative D-R would require vegetation clearing of 7,000 feet of centerline and Alternative E-R would require vegetation clearing of 4,000 feet of centerline on the edges of this unroaded area (ERO Resources Corp. 2010b). Alternatives D-R and E-R would not impact this area's overall size, character, or resource value. The Sedlak Park Substation and loop line would not affect unroaded areas.

3.24.3 Wild and Scenic Rivers

3.24.3.1 Regulatory Framework

Section 7 of the 1968 Wild and Scenic Rivers Act provides for the protection of the free-flowing, scenic, and natural values of rivers designated as components or potential components of the National Wild and Scenic Rivers System from the effects of construction of any water resources project. A water resources project under the Wild and Scenic Rivers Act is any activity that may affect the free-flowing characteristics of a designated or study river. The Wild and Scenic Rivers Act affords protection to two types of rivers: designated rivers, or Congressionally-authorized study rivers. The analysis area has no designated rivers or Congressionally-authorized study rivers.

The Forest Service's land management policies require a comprehensive evaluation of the potential for rivers to be eligible for inclusion in the Wild and Scenic River System (USDA Forest Service 2006a). In 1989, the KNF amended the KFP and identified the East Fork Bull River and the entire Bull River as eligible for addition to the National Wild and Scenic Rivers System. The 1989 KFP amendment established management standards to protect river values for eligible segments. Reasonable access for mineral-related purposes is allowed, subject to statutory restrictions such as the Wilderness Act and the Endangered Species Act. A KFP standard is that approval of Plans of Operations include requirements to minimize surface impacts.

River segments eligible for potential inclusion are not afforded protection under the Wild and Scenic Rivers Act. Forest Service policy for eligible river segments directs that "water resources projects proposed on a section 5(d)(1) study river [eligible river] are not subject to section 7(b), but will be analyzed as to their effect on a river's free-flow, water quality, and outstandingly remarkable values, with adverse effects prevented to the extent of existing agency authorities (such as special-use authority)" (USDA Forest Service 2006a).

The Bull River was listed on the Nationwide Rivers Inventory in 1993 (National Park Service 2009). The Nationwide Rivers Inventory is a listing of more than 3,400 free-flowing river segments in the United States that are believed to possess one or more "outstandingly remarkable" natural or cultural values judged to be of more than local or regional significance. A 1979 Presidential Directive requires federal agencies to protect and manage rivers on the Nationwide Rivers Inventory and the surrounding area in a fashion comparable to rivers already included in the Wild and Scenic Rivers System. The U.S. Council on Environmental Quality issued a 1980 Memorandum that stated: "Although the President's directive does not prohibit an agency from taking, supporting or allowing an action which would adversely affect wild and scenic values of a river in the Inventory, each agency is responsible for studying, developing and describing all reasonable alternatives before acting, and for avoiding and mitigating adverse effects on rivers identified in the Inventory."

3.24.3.2 Analysis Area and Methods

The eligible segments of the East Fork Bull River and the Bull River below the confluence with the East Fork Bull River are part of the analysis area for wild and scenic rivers (Figure 88). Other eligible segments of the Bull River system would not be affected. The analysis of effects on wild and scenic rivers was qualitatively based on direct effects on the free-flowing characteristics, water quantity, water quality, and outstandingly remarkable values of the eligible wild and scenic segments.

Data on the outstandingly remarkable values of the eligible wild and scenic segments were taken from the KNF's 2013 process to identify and classify potentially eligible wild and scenic rivers (USDA Forest Service 2013c, Appendix E). None of the transmission line alternatives would affect free-flowing characteristics, water quantity, water quality or outstandingly remarkable values of the eligible wild and scenic segments. Disclosure of effects on eligible segments is limited to the mine alternatives.

3.24.3.3 Affected Environment

Three eligible river segments of the Bull River are eligible for addition to the Wild and Scenic River System. A 3-mile segment of the East Fork Bull River in the CMW was identified as a Wild River. A 4.5-mile segment of the East Fork Bull River outside the CMW and a 9.1-mile eligible segment of the Bull River in the analysis area were identified as Recreational Rivers (Figure 88). The Outstandingly Remarkable Value of the three segments is scenery.

A wild river is a river or section of rivers free of impoundments and generally inaccessible except by trail, with watersheds or shorelines essentially primitive and waters unpolluted. These represent vestiges of primitive America. A recreation river is a river or section of rivers readily accessible by roads or railroad, which may have some development along their shoreline and which may have undergone some impoundments or diversions in the past. The qualities that contribute to each of the three segments' eligibility are scenic values.

3.24.3.4 Environmental Consequences

3.24.3.4.1 Alternative 1 – No Mine

The three eligible river segments would not be affected by mining activities.

3.24.3.4.2 Alternative 2 – MMC Proposed Mine

Free-Flowing Characteristics

Alternative 2 would not alter the free-flowing character of the East Fork Bull River or Bull River. Flow would remain in natural condition without impoundment, diversion, straightening, rip-rapping, or other modification of the stream.

Water Quantity

Changes in streamflow in Alternative 2 are discussed in section 3.11.4.3, *Alternative 2 – MMC Proposed Mine* in the *Surface Water Hydrology* section. The 3D model predicted flow in the East Fork Bull River and Bull River would be reduced in all mine phases, reaching a maximum reduction of 0.40 cfs in the East Fork Bull River at the CMW boundary and 0.33 cfs at the mouth of the East Fork Bull River and in the Bull River during the Post-Closure Phase. A permanent decrease of 0.01 cfs is predicted in the East Fork Bull River at the CMW boundary, and a flow increase of 0.05 cfs is predicted at the mouth of the East Fork Bull River and in the Bull River.

With the data currently available, the 3D model results provide a potential range of streamflow impacts. They are the best currently available estimates of impacts and associated uncertainty that can be obtained using groundwater models. The 3D groundwater flow model would be refined and rerun after data from the Evaluation Phase were incorporated into the models (see section C.10.4, Evaluation Phase in Appendix C). Following additional data collection and modeling, the predicted impacts on surface water resources in the analysis area, including simulation of mitigation measures, may change and the model uncertainty would decrease. See section 3.10.4.3.5, *Groundwater Model Uncertainty* in the *Groundwater Hydrology* section for more discussion of uncertainty.

Water Quality

Changes in water quality in Alternative 2 are discussed in section 3.13.4.3, *Alternative 2 – MMC Proposed Mine* in the *Water Quality* section. During all phases except post-closure, mine dewatering and the resulting drawdown of bedrock groundwater may reduce the flow of bedrock groundwater to surface water. East Fork Bull River may have lower concentrations of dissolved solids and metals. If such a water quality change occurred, it would be detectable only during low flow periods when bedrock groundwater is the major source of supply to surface water. Even at low flows, the changes in water quality may be difficult to measure.

Post-closure, groundwater levels would begin to recover, but water would continue to flow toward the mine void for hundreds of years. Eventually, water may begin to flow out of the underground mine workings and may mix with groundwater in saturated fractures, react with iron oxide and clay minerals along an estimated 0.5-mile or greater flow path, undergo changes in chemistry, and flow, without mitigation in Alternative 2 at a low rate as baseflow to the East Fork Bull River. The effect cannot be accurately quantified without additional information from the underground setting. It is likely that cadmium, lead, and copper minerals exist within bedrock fractures at low concentrations. To develop a quantitative estimate of the actual effect, MMC would monitor the chemistry within the underground workings, evaluate downgradient groundwater flow and chemistry within bedrock fracture systems, and monitor baseflow in the East Fork Bull River (see Appendix C, *Water Resources Monitoring*).

Outstandingly Remarkable Values

Reductions in streamflow or changes in water quality would have no effect on the scenic values of the East Fork Bull River or Bull River. Historic resources in the three segments, such as trails or the Bull River Guard Station, would not be affected. The scenic quality of the three segments would not be affected by a reduction in baseflow.

3.24.3.4.3 Alternative 3 – Agency Mitigated Poorman Impoundment Alternative and Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Free Flowing Characteristics

Alternatives 3 and 4 would not alter the free-flowing character of the East Fork Bull River or Bull River. Flow would remain in natural condition without impoundment, diversion, straightening, rip-rapping, or other modification of the stream.

Water Quantity

Changes in streamflow in Alternative 3 and 4 are discussed in section 3.11.4.4, Alternative 3 – *Agency Mitigated Poorman Impoundment Alternative* and section 3.11.4.5, Alternative 4 – *Agency Mitigated Little Cherry Creek Impoundment Alternative* in the *Surface Water Hydrology* section. The 3D model predicted flow in the East Fork Bull River and Bull River would be reduced in all mine phases, reaching a maximum reduction of 0.39 cfs in the East Fork Bull River at the CMW boundary and 0.32 cfs at the mouth of the East Fork Bull River and in the Bull River during the Post-Closure Phase. A permanent decrease of 0.01 cfs is predicted in all three stream segments. The agencies' mitigation of increasing the buffer zones near Rock Lake and the Rock Lake Fault which was not modeled, and leaving one or more barrier pillars inside the mine, is designed to minimize effects on East Fork Bull River streamflow and water quality.

Water Quality

Changes in water quality in Alternatives 3 and 4 are discussed in section 3.13.4.4, *Alternative 3 – Agency Mitigated Poorman Impoundment Alternati*ve and section 3.13.4.5, *Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative* in the *Water Quality* section. The effects on the three eligible segments in all phases except post-closure would be the same as Alternative 2. With the agencies' mitigation of barrier pillars if required in Alternatives 3 and 4, the flow would be toward East Fork Rock Creek and the post-mining changes in streamflow in the three eligible river segments would be minimized, and the water quality of the three segments would not be affected.

Outstandingly Remarkable Values

Reductions in streamflow or changes in water quality would have no effect on the scenic values of the East Fork Bull River or Bull River. The historic resources in the three eligible river segments, such as trails or the Bull River Guard Station, would not be affected. The scenic quality of the three segments would not be affected by a reduction in baseflow.

Effectiveness of Agencies' Proposed Mitigation

The agencies alternatives would effectively minimize effects on East Fork Bull River streamflow and water quality.

3.24.3.4.4 Transmission Line Alternatives

None of the transmission line alternatives, substation or loop line would affect the free-flowing characteristics, water quantity, water quality, or the outstandingly remarkable values of any of the three eligible segments.

3.24.3.4.5 Cumulative Effects

Past actions have not substantially altered the attributes of the CMW since the passage of the Wilderness Act or the establishment of the Cabinet Face East IRA. The existing Libby Adit is visible from some locations in the CMW and the Cabinet Face East IRA. Development of the reasonably foreseeable Rock Creek Project likely would have similar effects on wilderness and roadless areas as those described for development of the Montanore Project. The Rock Creek Project would not be visible from key viewpoints identified for the Montanore Project scenery analysis, but some components of both projects would be visible from some locations (see section 3.17.4.11, *Cumulative Effects,* in the *Scenery* section. Other viewpoints within the CMW would be affected by the Rock Creek Project. Wilderness visitors at some locations also may be affected by the clearing of timber for any of these future project facilities. The cumulative effects of the Rock Creek Project and the Montanore Project might contribute to a loss of wilderness character desired by some individuals.

The Rock Creek Project would not directly affect the Cabinet Face East IRA, the Rock Creek IRA or the McKay IRA and would not contribute to the cumulative effects on Cabinet Face East IRA. Libby Creek Ventures plans to drill three boring holes in the Libby Creek drainage outside of the Cabinet Face East IRA, which may increase activity and noise in the drainage and in nearby parts of the IRA for up to one week. About 1 acre of land is planned for clearing. This activity in combination with the Montanore Project may have a short-term adverse cumulative effect upon visitors to the IRA and the CMW.

The Montanore and Rock Creek Projects, assuming they occurred concurrently, would cumulatively reduce flow in the East Fork Bull River in the CMW. No other aspects of the two projects would have cumulative effects on surface water resources in the CMW or an IRA. The maximum effects on the East Fork Bull River would occur after both mines ceased operations (assumed to be operating and closing simultaneously). Compared to direct effects, cumulative flow reductions would be 0.08 cfs greater in the East Fork Bull River at the CMW boundary (Table 117). As the mine void filled and groundwater levels above the mines and adits reached steady state conditions, the effects on streamflow would decrease. Cumulative effects at steady state conditions were not quantified.

RCR prepared a 3D numerical hydrogeological model of the Rock Creek mine area to assist in defining potential impacts on groundwater and surface water resources (Hydrometrics 2014). For the Rock Creek Mine SEIS, the predicted cumulative effects were estimated by adding the results from the Montanore and Rock Creek 3D models for the respective periods of greatest groundwater drawdown. RCR's model predicted effects were slightly greater than estimated by MMC's 3D model (Table 117). Cumulative streamflow effects of the Rock Creek and Montanore projects are discussed in section 3.11.4.9, *Cumulative Effects* in the *Surface Water Hydrology* section; cumulative water quality effects are discussed in section 3.13.4.9, *Cumulative Effects* in the *Water Quality* section.

Cumulative reductions in streamflow would have no effect on the scenic values of the East Fork Bull River or Bull River. The historic resources in the three eligible river segments, such as trails or the Bull River Guard Station, would not be affected. The scenic quality of the three segments would not be affected by a reduction in baseflow.

3.24.3.5 Regulatory/Forest Plan Consistency

3.24.3.5.1 Wilderness

Valid existing rights were established to patents were issued to lode mining claims HR 133 and HR 134 in the CMW in 2001. None of the mine and transmission line alternatives would directly physically disturb any lands within the CMW and none of the four wilderness qualities would be directly affected. None of the alternatives would directly affect wilderness character. Under all alternatives, the undeveloped quality would not be affected because the wilderness would remain essentially without permanent improvements or modern human occupation.

The Wilderness Act does not regulate activities outside the wilderness that may affect wilderness character. None of the alternatives would indirectly affect the wilderness quality of undeveloped. The undeveloped quality would not be affected because the wilderness would remain essentially without permanent improvements or modern human occupation.

All mine alternatives have the potential to indirectly affect wilderness qualities of untrammeled, natural, and solitude or a primitive and unconfined type of recreation. Mitigation measures identified in Chapter 2 for Alternatives 3 and 4 and monitoring required for Alternatives 3 and 4 (Appendix C) would be implemented to minimize changes in wilderness character. Mitigation measures such as increasing the buffer zones near Rock Lake and the Rock Lake Fault, and the agencies' monitoring coupled with final design criteria submitted for the agencies' approval, would reduce the risk of subsidence and measurable hydrological indirect effects to the surface within the wilderness. In Alternative 3 and 4, potential air quality indirect impacts on wilderness lakes and wilderness character would be minimized by mitigation measures such as limiting generator use, and using tier 4 engines and low sulfur diesel fuel in underground mobile equipment by reducing emissions as compared to Alternative 2.

Mitigation measures and monitoring requirements in Alternatives 3 and 4 are reasonable stipulations for protection of the wilderness character and are consistent with the use of the land for mineral development. Alternatives 3 and 4 would be conducted to protect the surface resources in accordance with the general purpose of maintaining the wilderness unimpaired for future use and enjoyment as wilderness and preserving the wilderness character consistent with the use of the land for mineral development and production in compliance with 36 CFR 228.15 and the Wilderness Act. All mine and transmission line alternatives would comply with the Wilderness Act, meet the KFP wilderness goals, objectives and standards, and comply with 2009 Cabinet Mountains Wilderness Management Plan. Alternatives 3 and 4 would further minimize adverse environmental impacts on surface resources within the wilderness, and thereby comply with the regulations (36 CFR 228, Subpart A) for locatable mineral operations on National Forest System lands.

3.24.3.5.2 IRA

Mine Alternative 2 and transmission line Alternative B would directly impact 44 acres of the Cabinet Face IRA thru road construction and timber harvest. The roadless characteristics of the 44 acres of surface disturbance would not be preserved in Mine Alternative 2 and Transmission Line Alternative B. MMC has valid existing rights to access the minerals proposed for mining with the Montanore Project, and road construction and timber harvest in the Cabinet Face East IRA could be authorized by the Chief of the Forest Service.

Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R and E-R would not require road construction and timber harvest within an IRA. Effects of these alternatives would be from activities outside of the IRAs. Mine Alternative 3 and 4 and Transmission Line Alternatives C-R, D-R and E-R would comply with the KFP regarding management of affected IRAs. Alternatives 3 and 4 would minimize adverse environmental impacts on surface resources within the IRAs, and thereby comply with the regulations (36 CFR 228, Subpart A) for locatable mineral operations on National Forest System lands.

3.24.3.5.3 Eligible Wild and Scenic River Segments

None of the mine or transmission line alternatives would affect the free-flowing characteristics of the eligible portions of the Wild and Scenic River segments. Flow in the three eligible segments would remain in natural condition without impoundment, diversion, straightening, rip-rapping, or other modification of the stream. Mitigation measures identified in Chapter 2 for Alternatives 3 and 4 and monitoring required for Alternatives 3 and 4 (Appendix C) would be implemented to minimize changes in the water quality of the three eligible segments. Reductions in streamflow or changes in water quality would have no effect on the scenic values of the East Fork Bull River or Bull River. All alternatives would comply with the Wild and Scenic Rivers Act, Forest Service policy, and the KFP regarding eligible Wild and Scenic River segments.

3.24.3.6 Irreversible and Irretrievable Commitments

Any changes to baseflow in the East Fork Rock Creek and East Fork Bull River within the CMW during and after mining would be an irreversible commitment of resources. Wilderness experiences for some visitors may be irretrievably affected from specific viewpoints within the CMW under any of the alternatives. Alternative 2 and MMC's proposed North Miller Creek transmission line alternative would irretrievably devote small portions of the Cabinet Face East IRA to mining uses over the life of the project. Roadless area attributes would be irretrievably affected in the Libby Creek and Ramsey Creek drainages in all alternatives. All alternatives would irreversibly reduce streamflow in the eligible East Fork Bull River and Bull River Wild and Scenic River segments.

3.24.3.7 Short-term Uses and Long-term Productivity

In the short term, development of the project under Alternative 2 would affect the consideration of a small portion of the Cabinet Face East IRA in the Ramsey Creek drainage for permanent designation as wilderness during the project's life due to the project facilities' direct disturbance of the IRA. In the long term, areas that were cleared of timber for facilities would be visible from a number of key viewpoints, both in the CMW and the Cabinet Face East IRA, resulting a long-term impact on the visual quality of some visitor's experience.

3.24.3.8 Unavoidable Adverse Environmental Effects

Under Alternative 2, noise levels would be increased from the Ramsey Plant Site up to the ridge between Elephant Peak and Bald Eagle Peak in the CMW. Under Alternatives 3 and 4, noise levels would increase from the Libby Plant Site up to the ridge between Elephant Peak and Ojibway Peak. Under all alternatives, night lighting would be visible from some locations of the CMW. All mine and transmission line action alternatives would indirectly reduce the opportunities for solitude in both the CMW and the Cabinet Mountains East IRA. The three wilderness qualities of untrammeled, natural, and solitude or a primitive and unconfined type of recreation in certain areas also would be indirectly affected in all action alternatives. Under Alternative 2, primitive recreation opportunities would no longer exist in the Ramsey Creek drainage within the IRA due to the unavoidable physical impacts, presence of facilities, increased noise levels, and night lighting.

3.25 Wildlife

3.25.1 Introduction

The KNF provides habitat for more than 300 different species of wildlife (USDA Forest Service 2003c), many of which occur on the Libby Ranger District (District) and within the Montanore Project analysis area. The presence or absence of wildlife species depends in part on the amount, distribution and quality of habitat used by each species. Successional and structural changes in habitat, as well as natural predation, hunting or trapping can impact species distribution and population numbers.

This section is comprised of six subsections: key habitats, MIS, Forest Service sensitive species, federal threatened and endangered species, migratory birds, and other species of interest, namely moose and Montana Species of Concern. Wildlife resources selected for detailed analysis represent a combination of fine filter (species-specific) and coarse filter (management indicator species) analyses. Management Indicator Species (MIS) are identified in the KFP and represent a particular habitat or habitat complex. Effects on Forest Service sensitive species, which are designated by the Regional Forester, also are disclosed. The evaluation of wildlife effects in the analysis area is concurrent and interdependent with the ESA Section 7 consultation process. The effect of a proposed activity on any wildlife species is largely dependent on the duration of its effects. Three potential categories of effects are: (1) a short-term event whose effects are relaxed almost immediately (pulse effect), (2) a sustained, long-term, or chronic event whose effects are not relaxed (press effect), or (3) a permanent event that sets a new threshold for some feature of a species' environment (threshold effect) (USFWS and National Marine Fisheries Service 1998). For the wildlife subsections, short-term effects were considered to be 2 to 5 years, while long-term effects would last for the life of the mine (30 years) or longer. These definitions are not consistent with those provided in section 3.1.1, Direct, Indirect, and Cumulative Effects (p. 267), but are more appropriate for analysis of wildlife in general due to life history, reproductive cycles and population dynamics specific to each species The evaluation of impacts on Montana Species of Concern is part of the MFSA transmission line certification process.

The analysis area for each species was determined based on viability analysis and concepts described by Ruggiero *et al.* 1994, which considers biological populations and ecological scale. Evaluation of species viability is based on concepts and direction provided in the KNF Conservation Plan (Johnson 2004a), and the Wildlife Habitat Assessment for the Kootenai and Idaho Panhandle Plan Revision Zone (Ecosystems Research Group 2012). The analysis area used for an individual species may vary from other resource sections, or between different species of wildlife, based on biological needs and/or direction provided for T&E species under the ESA.

Depending on the wildlife resource, the analysis area considers all or portions of the six PSUs impacted by the proposed activity: Rock, Treasure, Crazy, Silverfish, McElk, and Riverview PSUs. The size of a PSU is sufficient to cover home ranges of wildlife species considered in this analysis and to determine the effects of the mine and transmission line alternatives.

The majority of the proposed and alternative mine facilities, as well as a portion of the proposed and alternative transmission line alignments would be located within the Crazy PSU while the remaining segments of the transmission line alignments would be located within the Silverfish PSU. Except where noted in the *Analysis Area and Methods* subsection, such as for snags, woody debris, and T&E species, only the Crazy and Silverfish PSUs were evaluated for direct, indirect and cumulative effects to individuals and their habitat on the KNF.

In PSUs other than Crazy and Silverfish, effects would be minor. One acre or less of private land in the Rock PSU would be impacted by the Rock Lake Ventilation Adit. A short segment of the Bear Creek Road, which would be widened for its proposed as the main access road, would pass through the southeast tip of the Treasure PSU on National Forest System lands. Only private land within the McElk and Riverview PSUs would be physically affected (vegetation clearing or road construction) by the eastern segments of the transmission line alternatives. Effects in the Rock, Treasure, McElk, and Riverview PSUs will also be quantified if those effects are important to the species or their habitat.

To evaluate potential direct, indirect and cumulative impacts of the transmission line on private and State lands outside of the Crazy and Silverfish PSUs, the analysis area includes all land within a corridor 1 mile on each side of the alternative transmission line alignments. The 1-mile buffer adjacent to the transmission line alignments was guided by Circular MFSA-2 (DEQ 2004). Potential impacts on wildlife resources on private land are evaluated qualitatively in each subsection and are not included in most habitat calculations conducted to assess compliance with numeric standards, objectives, and guidelines in the KFP. Habitat data on private land were considered in the analysis where available.

Analysis areas for threatened and endangered species are based on management areas defined in recovery plans or other areas, such as those defined by the NRLMD or Grizzly Bear Access Amendment. To provide information about the relative magnitude of anticipated effects of the Montanore Project alternatives, impacts on wildlife habitat were estimated to the nearest acre; uncertainties in the habitat mapping and impact analysis models are beyond this level of precision.

3.25.2 Key Habitats

Key habitats provide aquatic and/or vegetative characteristics, or combinations of characteristics, which may distinguish them from surrounding habitats or may be found as a component within a variety of broader habitat types. The characteristics of these habitats play a role in the survival and success of many wildlife species, although their importance varies by species. This section describes the characteristics and importance of cavity habitat provided by snags and down woody debris and analysis of effects based on the proposed alternatives. Old growth forests, riparian areas, and wetlands, which are also key habitats for some species, are discussed in sections 3.22, *Vegetation,* 3.6, *Aquatic Life and Fisheries,* and 3.23, *Wetlands and Other Waters of the U.S.* Effects to wildlife regarding the availability of cavity habitat and down woody debris are evaluated within the analyses for species associated with these key habitats, such as pileated woodpecker discussed in section 3.25.3*, Management Indicator Species* and flammulated owl, fisher, and western toad discussed in section 3.25.4, *Forest-Sensitive Species.*

3.25.2.1 Regulatory Framework

3.25.2.1.1 Organic Administration Act and Forest Service Locatable Minerals Regulations

The Organic Administration Act authorizes the Forest Service to regulate the occupancy and use of National Forest System lands. The Forest Service's locatable minerals regulations are promulgated at 36 CFR 228, Subpart A. The regulations apply to operations conducted under the U.S. mining laws as they affect surface resources on National Forest System lands under the jurisdiction of the Secretary of Agriculture. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources. 36 CFR 228.8 also requires that mining operators take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations.

3.25.2.1.2 National Forest Management Act/Kootenai Forest Plan

The National Forest Management Act requires the Secretary of Agriculture to promulgate regulations specifying guidelines for land management plans that "provide for the diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet overall multiple-use objectives…" The "specific land area" (scale) for providing diversity is established in the framework as the area covered by the Forest Plan, or the entire KNF. One of the KFP goals is to "maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species… and in sufficient quality and quantity to maintain habitat diversity representative of existing conditions" (II-1 #7).

KFP direction for maintaining viable populations of cavity-dependent species is derived from Thomas (1979), which describes snag levels necessary to maintain self-sustaining populations of a species. The direction is to maintain habitat capable of providing for at least 40 percent of the potential population level (PPL) of cavity dependent species throughout commercial forest lands and at least 60 percent of the PPL in riparian areas (KFP II-22 and A-16). The PPL is equated with snag level, or the intensity of snag management on a landscape. Snag densities of about 0.9 and 1.35 snags per acre are required to maintain snag levels for 40 and 60 percent of the PPL, respectively (KFP A-16-4). In order to provide a continuous supply of snags over time, there is also a need to designate green trees as snag replacements. Usually two replacements are needed for every snag needed (KFP A-16-11). This results in the general recommendation of one to two snags and two to four snag replacements per acre, or a total of three to six per acre.

The KFP contains minimal direction concerning down woody debris. It directs that sufficient amounts of large down woody debris be retained on site for wildlife habitat needs, nutrient release back into the soil, and site protection for timber stand regeneration. Forest-wide management direction (KFP A 16-6) is to meet Timber/Silviculture Guideline #9, which is to leave logs greater than 12 inches in diameter scattered throughout dozer-piled timber units (a few pieces/acre) to provide cover and feeding sites for birds and small mammals. Five to 15 tons/acre is recommended.

3.25.2.1.3 Major Facility Siting Act

The MFSA directs the DEQ to approve a facility if, in conjunction with other findings, the DEQ finds and determines that the facility would minimize adverse environmental impacts, considering the state of available technology and the nature and economics of the various alternatives. The DNRC and FWP are required to report to DEQ information relating to the impact of the proposed site on FWP's area of expertise. The report may include opinions as to the advisability of granting, denying, or modifying the certificate.

3.25.2.2 Snags and Woody Debris

On the KNF, 42 species of birds, 14 species of mammals, and several species of amphibians are recognized as largely dependent on cavity habitat (KFP, A 16-2). Cavity habitat can be found in snags (standing dead trees), broken topped live trees, live cull trees, and down logs and are used by a variety of wildlife species for nesting, denning, perching, roosting, foraging, and shelter. Snags provide the primary substrate for those species excavating their own cavities as the wood has generally been softened by decay (Bull *et al*. 1997).

Tree mortality is an inevitable outcome within a forested stand. The agent of mortality as well as age, size, distribution, and longevity of the resulting snags are not as predictable. Snags are created by events such as insect and disease, wildfire, physical damage, weather, over-crowding, or simply from old age. They are lost by falling down, through both natural (*e.g.,* decomposition and wind) and human mechanisms (*e.g.*, woodcutting, and timber harvest).

Primary cavity excavators such as pileated woodpeckers and northern flickers excavate new cavities during activities such as feeding, nesting, roosting, and drumming. These in turn are used by secondary cavity users who cannot excavate their own cavities and must depend on those already created. Providing adequate suitable habitat for primary excavators ensures that viable populations of all cavity-dependent species would be supported.

Down woody debris is an important component of forest ecosystems, providing for soil protection and productivity as well as wildlife habitat (*e.g.,* cover, reproduction, and foraging opportunities) for a wide variety of birds, mammals, reptiles, and amphibians. This dead, woody material is derived from trees in various stages of decay and any material larger than 3 inches in diameter is considered coarse woody debris (Graham *et al*. 1994). The most beneficial form of woody debris for wildlife is logs, which to qualify as a log must measure a minimum of 8 feet long with a large-end diameter of 6 inches or more (Bull *et al*. 1997). The larger the log, the greater the longevity and opportunities it provides for wildlife (Thomas 1979, Bull *et al*. 1997, Brown *et al*. 2003) although the retention of small material is better than none (Thomas 1979). The ecological processes and functions of down wood material are discussed in many research papers (*e.g.*, Bull *et al*. 1997; Graham *et al*. 1994; Maser and Trappe 1984; Maser *et al*. 1988).

In summary, the planning subunits (PSUs) in which proposed Montanore Project activities would occur are currently providing high PPLs of 73 to 91 percent for cavity dependent species. These PPLs are well above the 40 and 60 percent standards for upland and riparian habitats, respectively, and there would be negligible to minimal impacts from proposed activities. Snags and down woody debris would be maintained at a sufficient level within the impacted PSUs to provide for viable populations of cavity dependent species in the analysis area. In addition, the agencies' alternatives would retain snags unless required to be removed for safety or operational reasons within the disturbance areas as well as down woody materials beneath the transmission lines at levels recommended for both soil productivity and wildlife habitat as appropriate for the habitat type.

3.25.2.2.1 Analysis Area and Methods

The analysis area for snags includes the four PSUs impacted by proposed activities: the Crazy, McElk, Riverview, and Silverfish PSUs. The majority of the proposed and alternative mine facilities, as well as a portion of the proposed and alternative transmission line alignments would be located within the Crazy PSU while the remaining segments of the transmission line alignments on National Forest System lands would be located within the Silverfish PSU. Therefore, the bulk of the following analysis focuses on these two PSUs. Some segments of the transmission line alignments, substation and loop line would occur within small areas on private land of the McElk and Riverview PSUs. Using the PSU to analyze the potential effects to snag and down wood habitat on private lands provides for both consistency with the scale of analysis used for effects occurring on National Forest System lands as well as context for how many acres of private lands are being impacted compared to what is available within a similar sized analysis area. None of the mine or transmission line alternatives would affect snag and down wood habitats within the Treasure PSU because only road improvement work on an existing open road would occur within it. Therefore, this PSU has been eliminated from further analysis and the proposed road location and existing PPL can be found in the project record. Also eliminated from further analysis was the Rock PSU as less than 1 acre of private land on steep, rocky ground would be affected by the Rock Lake Ventilation Adit.

The analysis area includes National Forest System land as well as private and State lands. Calculations of the PPL and estimates of the impacts to down woody material on National Forest System lands are based on forest vegetation data, past vegetation management treatments (type and date of implementation), the restricted and open road system, and disturbance area boundaries of each of the mine and transmission line alternatives. Information from FACTS, including treatment type and year of completion, and summaries of Vegetation Response Units (USDA Forest Service 1999c) were also used to estimate snag densities. District surveys for old growth and post-harvest units provide additional data sources for cavity and down wood habitat conditions. For the Crazy PSU, data sources for snag and down wood habitat include District surveys for old growth and harvested units that cover about 7,502 acres. Survey methods/procedures for old growth and harvest units are found in section 3.22, *Vegetation*, and the project record, respectively. Quantitative snag and down wood information is not as readily available for private or state-owned lands in the analysis area, much of which has been logged in the past 20 to 30 years. Current snag and down wood availability on private and State land was estimated based on vegetation mapping shown on Figure 85 and likely past and current land use practices.

Thomas (1979) was used to determine the percent PPL of National Forest System lands within the analysis area. This process uses a weighted calculation (percent snag level X percent of the PSU with that snag level) that considers management and other activities as well as natural events (*e.g.*, wildfire, insect and disease outbreaks, etc.) to estimate current PPL and change due to proposed activities as displayed in Table 189. Old growth existing condition acres and acres impacted by proposed activities are not directly comparable to those found within section 3.22.2, *Old Growth Ecosystems*, due to different analysis methods. This analysis includes 100 percent of all identified old growth acres regardless of classification, includes acres above 5,500 feet, and does not include acres within close proximity of open roads to account for snag loss to firewood gathering. Meeting the KFP riparian standards, as amended by INFS (USDA Forest Service 1995), would ensure provision of adequate snags and replacement trees to meet the riparian 60 percent snag level direction. However, all alternatives would result in disturbance to riparian habitats and the analysis considers the impacts to maintaining 60 percent primary cavity excavator PPL on National Forest System lands within this habitat.

The value applied to an activity type is founded on the following assumptions based on Thomas (1979) and KNF snag data analyses. These assumptions are applied as a worst-case scenario and described below and in the footnotes of Table 189. See Table 189 for snag levels applied to activity type and references. Harvest type and period of implementation influence the number of snags left standing in the treated area. Unharvested and old growth stands provide 100-percent snag levels. For the Supplemental Draft EIS and Final EIS, the areas of overlap between mapped old growth and harvest stands were considered old growth habitat. As a result, the area of partial cut stands differs from the Draft EIS. Partial cut stands provide a higher snag level than regeneration harvest methods and regeneration harvests implemented after the KFP retain more snags than those implemented prior (Johnson and Lamb 1998). Firewood cutting within 200 feet of open roads has resulted in some snag loss. However, Tincher (1998) reported this impacted area still provides at least 40 percent snag level compared to unroaded areas of similar habitat type. Similarly, Bate and Wisdom (2004) found there is no difference in snag density adjacent to open versus closed roads although densities were lower in areas closer to a town. Forest-wide, visual observations suggest that snag levels adjacent to roads can be as low as zero. Since firewood cutting is allowed from any open road, retention of snags within 200 feet of the road over time is highly unlikely. Therefore, a worst-case scenario was used where areas within 200 feet of open roads were considered to have total snag loss. Snag loss associated with restricted roads was limited to the roadbed itself.

Impacts on cavity and down wood habitats discussed in the Environmental Consequences section are based on the expected disturbance areas associated with the various project features of the mine and transmission line alternatives. Not all proposed disturbance acres would result in a reduction in the cavity habitat PPL as it depends on the habitat condition in which the clearings would take place. For example, road improvements occurring within existing open road prisms likely would not reduce cavity and down wood habitat and these disturbance acres would not be counted again. Conversely, clearings occurring in old growth or previously untreated stands would have the greatest potential reduction in cavity and down wood habitat changing the snag level from 100 to 0 percent. Those acres determined to affect the PPL are the “disturbance acres” associated with each habitat condition in Table 190; total disturbance acreage is also provided for each alternative. The effect indicators for management level includes the percent of the maximum PPL by PSU relative to the 40 and 60 percent standards for upland and riparian habitats and acres impacted that reduce snag levels.

Since Thomas (1979), new science as summarized in Bull *et al*. (1997) indicate that snag densities need to be increased for variables such as larger woodpecker home ranges, foraging structure, and other secondary uses such as loose bark that Thomas (1979) did not account for. New Forest Inventory and Analysis (FIA) data since implementation of the KFP have been incorporated into a Region One report on snag densities for western Montana (Bollenbacher *et al*. 2009). Bollenbacher *et al*. (2009) used FIA data to estimate snag density based on habitat type groups. Although this report provided snag information to be considered by the Forests, such as providing a guideline for managed snag levels, it does not set forth mandatory or required direction. Based on data for western Montana forests, and specifically to the KNF, snag densities required to achieve 40 and 60 percent snag levels are greater than KFP direction. These snag densities were considered in this analysis.

Data sources for down woody debris consist of District old growth and harvest unit associated surveys and predominant habitat type groups (correlated with VRUs) within the PSUs. Untreated stands would generate down woody material associated with the habitat type. However, in general, current down wood levels are generally considered to exceed historical levels due to longer fire return intervals within stands (Graham *et al*. 1994, Brown *et al*. 2003). Moist VRUs provide productive conditions for tree establishment and growth, which contribute to future down wood materials. This coupled with fire suppression, which has produced an accumulation of both down and standing materials, can result in high level of woody debris within forested stands. Based on the growing conditions and lack of large fires due to fire suppression, and high levels of down wood debris found within survey units it can be inferred that high levels of down wood material is available within the PSUs. Issue indicators are the relative reduction in expected down woody debris based on existing down woody debris available and design features for retaining down wood material within proposed activity areas.

3.25.2.2.2 Affected Environment

Three habitat type groups are found on the KNF and in the impacted PSUs: dry, low to mid elevation moist, and subalpine. The habitat type groups are described in Bollenbacher *et al*. (2009). The dry habitat type has the lowest density of snags, especially in the larger diameter classes due to more frequent, low- to mid-severity fires. Predominant trees are ponderosa pine and Douglas-fir on the drier sites with western larch found within the moister range of this type, all of which are preferred species for primary excavators and secondary cavity nesters. The low and mid moist habitat type is diverse in conifer species and include western larch snags in the early and late seral forest condition, with cedar and grand-fir also providing cavity habitat. This group has the highest density of snags of all size classes. The wet sites increase productivity and periodic mixed severity fires between stand replacing fires encourages the growth of large trees. Finally, the subalpine habitat type has high diversity of species depending on elevation and cold tolerance. Some sites are too cold for western larch and Douglas-fir. Fire frequencies can vary depending on the site composition and location. Snag density is high in the small diameter class and moderate in the larger classes compared to the other habitat types. Snag density, distribution, and longevity can be affected by timber harvest and human access in timber managed areas and possibly climate change and fire suppression in unmanaged areas (*e.g.,* wilderness or roadless) (Bollenbacher *et al*. 2009).

Stands experiencing insect, disease, or severe wildfire could have more than 2.25 snags per acre depending on the severity of the outbreak or fire that the stand receives. Within the analysis area, insect and disease generally appear to be at an endemic level with some slightly larger areas of activity at the southern end of the Silverfish PSU (USDA Forest Service *et al*. 2013) and there are no large areas of snags resulting from these processes. The last large fires occurred between 1885 and 1939, with the 1910 fires affecting large areas of the Crazy and Silverfish PSU leaving limited large tree component and little diversity or heterogeneity across the landscape. Snag levels within the fire perimeter would have been relatively high immediately following the fires, especially in high severity fire areas. However, snag longevity following fires depends on the species, size, and density and most are gone within 20 years (Bull *et al*. 1997, Morrison and Raphael 1993, Harris 1999, Russell *et al*. 2006). Estimating snag densities in these areas is difficult as the fire severity would not be the same throughout the fire perimeter. Some trees would have fallen, others remain, new snags would have been created from remaining trees, and newly established seedlings could reach 10 inches dbh by 60 years (USDA Forest Service 1993b). Harris (1999) included areas where the primary action on the stand is a natural process such as these as "uncut." Also, potentially high levels initially, followed by potentially low levels, would also likely be averaged out across the analysis area depending on the acres impacted. Therefore, fire areas where past timber harvest has not occurred were included in the old growth and unharvested acres in Table 189 and received a managed snag level of 100 percent.

Table 189 summarizes the existing PPL on National Forest System lands in the analysis area PSUs. Snag levels were determined based on the assumptions from the analysis method section above. The existing snag level on National Forest System lands in the analysis area range from about 73 to 91 percent and are well above the current KFP standard and/or guideline of 40 and 60 percent for upland and riparian habitats. Refer to the project record for details.

Table 189. Existing Potential Population Level on Timbered National Forest System Lands in the Analysis Area.

Habitat Condition[1]	Acres	Proportion of National Forest System Lands (%)	Total Snags per Acre[2]	Snag Level (%)	PPL[3] (%)
Crazy

[1] Includes VRUs 1, 2, 3, 4, 5, 6, 7, 9, 10, and 11. Based on timbered lands and does not include the following habitat types: grassland steppe, mountain bottomlands, agricultural lands, rural/urban, rock/scree/ice, and water.
[2] Snag density includes all snags ≥ 10” dbh (Thomas 1979). This density is needed to achieve the corresponding snag level value.
[3] Proportionate PPL equals percent National Forest System lands multiplied by percent snag level. Sum of proportionate PPLs from all habitat conditions equals the PSU PPL (Thomas 1979).
[4] Based on Tincher (2003).
[5] Based on Johnson and Lamb (1998).
[6] Partial cut harvests include, but are not limited to, improvement harvest treatments.
[7] Regeneration harvest includes, but is not limited to, clear cut with reserves, seed tree, and shelterwood harvest treatments.
[8] Roads include an average width of 33 feet; open roads were buffered by 200 feet to account for loss due to firewood gathering.
[9] Based on Tincher (1988), Bate and Wisdom (2004), and KNF forest-wide observations for worst case scenario.

The most recent KFP Monitoring Report addressing cavity habitat (Item C-6) is from fiscal year 2007 (USDA Forest Service 2008c). This report shows that over the last 5 years, 72.6 percent of the individual harvest units met KFP standards and 100 percent of the 33 compartments analyzed met or exceeded KFP standards for cavity habitat. The fiscal year 2005 monitoring report provided estimates of snag density on the KNF and looked at two size categories of snags: 10.0 to 19.9 inches dbh and those 20 inches or greater. Snags ranging between 10.0 and 19.9 inches are estimated to occur at a density of 10 snags per acre (8.3 to 11.7 snags per acre with a 90 percent confidence interval). Snags at least 20 inches in diameter are estimated to occur at a density of 1 snag per acre (0.8 to 1.2 snags per acre with a 90 percent confidence interval). Overall, monitoring indicates that the KNF is providing cavity habitat at a level sufficient to maintain viable populations of cavity-dependent species (40 percent or more of the PPL). Meeting Forest riparian standards, as amended by INFS, would assure the 60 percent level is being met in those areas.

The major VRU found in the vegetation analysis area is VRU5 (both VRS5S and VRU5N), which are moderately cool and moist ecosystems (see section 3.22, *Vegetation*). This VRU contains productive land types and moderate to high precipitation, providing environmental conditions favorable to vegetative growth (Gautreaux 1999) and, therefore, potential volumes of down woody debris. Both wildfire and vegetation management influence the levels of down wood debris within treated stands.

Historically, wildfires have played a large role in the amount of down wood in the forests (Graham *et al.* 1994). Depending on the frequency, intensity, and magnitude of fires, ponderosa pine forests could have more than 45 tons per acre of down wood while western white pine forests could have more than 268 tons per acre of down wood. The longer period of time between fires, the longer the down wood would remain. During the last 100 years, the frequency of fires in the northern Rocky Mountains has been greatly reduced, potentially resulting in larger amounts of down wood. Vegetation management treatments, primarily timber harvest, before the KFP would have reduced the amount of down woody debris available within the treated stands whereas vegetation management occurring post-implementation of the KFP would have been designed to maintain the recommended tons per acre. Results of down wood surveys in the Crazy and Silverfish PSUs suggest that the KFP guidelines of 5 to 15 tons of down wood per acre are being met in old growth and past harvest areas. Surveyed old growth stands average over 23 tons per acre and past harvest units averaged 41 tons per acre in the Crazy PSU. These estimates only included materials greater than 10 inches dbh, which identified the larger material more beneficial for wildlife use. It is likely that smaller materials were also present, contributing to a higher level of down wood available across the landscape than what was estimated. Therefore, the National Forest System lands within the analysis area currently provide for a variety of species that utilize down woody habitat, including the pileated woodpecker (see pileated woodpecker discussed in section 3.25.3*, Management Indicator Species*), and the existing down wood habitat level in the analysis area is expected to provide adequate suitable habitat for other dependent species.

The majority of the private and State lands impacted by the proposed transmission line, substation and loop line is heavily roaded and has been logged in the past 20 to 30 years (Figure 85 and project record). Also, the protection of riparian habitats on these lands is likely less stringent or may not occur compared to vegetation management activities on National Forest System lands and the retention of snags and down wood material is not expected to occur to the same level. As a result, existing levels of cavity and down wood habitat is likely to be less available on private and State lands.

3.25.2.2.3 Environmental Consequences

The Montanore Project's mine and transmission action alternatives would generally result in the clearing of vegetation to allow for the construction of proposed infrastructure. The acres reduced and resultant level of impact on the cavity habitat PPL and amount of down wood debris depends on where the activities would occur and what the existing habitat condition is there. Overall, proposed activities that result in the reduction of forested stands are expected to slightly reduce both snag and down wood debris levels within the impacted PSUs. As a worst case scenario, it was assumed that the clearings would result in a snag level of 0 percent and that all down wood debris would be removed. Mitigation for the agencies' alternatives would maintain some level of existing cavity and down wood habitat within clearings (see section 2.5.7.4.4, *Key Habitats* and section 2.9.6.1, *Down Wood Habitat*).

Clearing of all snags within the disturbance area would result in the loss of cavity habitat for the life of the mine and for some time following reclamation. For wildlife species that utilize large diameter snags and heavier canopy cover, it would take an estimated 125 to 150 years for the cavity habitat to recover to a condition where it may be used. For other species that will use smaller trees and a more open canopy condition, recovery and use would likely occur within 60 years. Similarly, for those species that require large amounts of down wood, especially large diameter wood structure, it would take many years for disturbed sites to grow and accumulate this material on the forest floor. For effects to wildlife associated with these habitat types, please see the following species' analyses.

The effects to cavity habitat and the change to the PPL on National Forest System lands within the Crazy and Silverfish PSUs are displayed in Table 190 and Table 192 for the mine and transmission line alternatives, respectively, and are further described in the following subsections. No activities would occur on National Forest System lands within the McElk and Riverview PSUs (see project record). Within the Crazy, Silverfish, McElk, and Riverview PSUs, private and State lands impacted by the transmission line, substation and loop line are discussed separately.

Alternative 1 – No Mine

No direct effects from federal actions would occur. The No Mine Alternative would maintain the existing vegetative condition on the landscape and wildlife use of cavity and down wood habitat would continue at current levels. Although past timber harvests and other vegetation management treatments resulted in a decrease in the amount of both habitats available, especially in some existing regeneration harvest units, both District and Forest level monitoring indicates that current levels meet KFP standards. Also, current down wood levels are generally considered to exceed historical levels due to longer fire return intervals within stands (Graham *et al*. 1994, Brown *et al*. 2003). The addition or loss of snags would depend on other factors, such as firewood cutting, wind events, natural attrition, or wildfire. The level of impact from these factors cannot be calculated due to the high uncertainty in predicting occurrence and intensity levels. Similarly, this alternative would not change the current condition or availability of down woody debris within the PSUs.

Table 190. Impacts on Cavity Habitat and Potential Population Level on Timbered National Forest System Lands in the Crazy PSU by Mine Alternative.

Habitat Condition[1]	Existing Acres	Disturbance Acres	Post Activity Acres	Proportion of NFS Lands (%)	Total Snags per Acre[2]	Snag Level (%)	PPL[3] (%)

[1] Includes VRUs 1, 2, 3, 4, 5, 6, 7, 9, 10, and 11 and does not include the following habitat types: grassland steppe, mountain bottomlands, agricultural lands, rural/urban, rock/scree/ice, and water.
[2] Snag density includes all snags ≥ 10” dbh (Thomas 1979). This density is needed to achieve the corresponding snag level value.
[3] Proportionate PPL equals percent National Forest System lands multiplied by percent snag level. Sum of proportionate PPLs from all habitat conditions equals the PSU PPL (Thomas 1979).
[4] Based on Tincher (2003); [5] Based on Johnson and Lamb (1998).
[6] Partial cut harvests include, but are not limited to, improvement harvest treatments.
[7] Regeneration harvest includes, but is not limited to, clear cut with reserves, seed tree, and shelterwood harvest treatments.
[8] Roads include an average width of 33 feet and were buffered by 200 feet to account for loss due to firewood gathering.
[9] Based on Tincher (1988), Bate and Wisdom (2004), and KNF forest-wide observations for worst case scenario.
[10] Existing restricted and open roads would generally still be located on the landscape; the displayed reduction in acres is to reflect the overlap in disturbance area and reallocation to the alternative’s disturbance acres.
[11] Worst-case scenario that assumes all snags would be removed with the vegetation clearing, although mitigation plans would be implemented under the agencies’ alternatives to maintain snags, unless required to be removed for safety reasons.

Alternative 2 – MMC Proposed Mine

All proposed mine activities that would impact snag and down wood debris would occur within the Crazy PSU. Disturbance for Alternative 2 would include facility (tailings impoundment, plant site, and other) and road construction. Most of the disturbance would occur on National Forest System lands, although some private land owned by the mine would be disturbed (Figure 78). Approximately 2,282 acres of the total 2,582 acres would occur within the habitat conditions identified in Table 190. Snags would be cleared within the disturbance boundaries for Alternative 2 and result in a snag level of 0 percent; however, not all proposed clearing acres would affect the cavity habitat PPL due to their location within a previously managed area.

The effect of the vegetative clearing in Alternative 2 within the Crazy PSU would be a reduction in the PPL of 1.2 percent from 73.2 to 72.0 percent. Approximately 644 acres of disturbance would occur within old growth and untreated stands, resulting in a change in the snag level from 100 to 0 percent on these acres. These two habitat conditions would continue to comprise 69.0 percent of the PSU and these moist habitats provide snag levels on the KNF in the range of 6.3 to 17.1 per acre (Bollenbacher *et al*. 2009). Therefore, the cavity habitat PPL would remain well above the 40 percent level recommended in the KFP for upland habitats. Alternative 2 would impact 249 acres of riparian habitat on National Forest System lands and is a reduction of 3.0 percent of riparian habitat available within the Crazy PSU and is minor at the PSU scale (Table 191). Also, Alternative 2 would not comply with a number of riparian area standards, which are discussed in section 3.6.4.11.4, *National Forest Management Act/Kootenai Forest Plan* (RF-2 through RF-5), beginning on p. 453. The feasibility of MMC's proposed Wetland Mitigation Plan to replace the lost functions of all potentially affected wetlands is uncertain. MMC's plan is conceptual and would be refined during the 404 permitting process. MMC did not update its mitigation plan for Alternative 2 to reflect new wetland and stream mitigation regulations and procedures. Section 3.23, *Wetlands and other Waters of the U.S.*, discusses proposed wetland mitigation in more detail. Therefore, Alternative 2 may not meet the riparian standard for snag levels (60 percent) within the immediate area of the disturbance. However, riparian habitats throughout the remainder of the PSU that are not impacted by Alternative 2 is expected to continue to meet the 60 percent standard through adherence to KFP riparian standards and the effect would be minimal at the PSU scale. Alternative 2 would result in the loss of all down wood on 2,282 acres on National Forest System land in the Crazy PSU. This estimated reduction of down woody material would be minor as it would occur on 3.7 percent of the timbered lands within the PSU (Table 190). Down wood levels, on average, is expected to exceed KFP standards within the Crazy PSU for dependent wildlife species based on: 1) the predominant habitat type within the disturbance area, 2) the amount of old growth and untreated stands within the PSU, 3) the existing level of down wood as supported by District surveys, and 4) because current down woody debris levels are generally considered to exceed historical levels due longer fire return intervals within stands (Graham *et al*. 1994, Brown *et al*. 2003).

Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Table 191. Riparian Habitat on National Forest System Lands Impacted by Proposed Mine Activities within the Crazy PSU.

PSU	Alternative 1/ No Mine	Alternative 2 (Acres	%)	Alternative 3 (Acres	%)	Alternative 4 (Acres	%)
Crazy	0	249	(3.0%)	195	(2.4%)	206	(2.5%)

Percents shown represent percent of available riparian habitat in entire PSU

The types of activities proposed under this alternative are similar to Alternative 2. Similar facility and road construction activities would occur, but there would be no LAD Areas associated with Alternative 3 and the tailings impoundment would be located slightly to the south and found entirely on National Forest System lands. The disturbance area surrounding the Poorman tailings impoundment would be smaller than the Little Cherry Creek impoundment disturbance area proposed in Alternative 2 by 656 acres.

Within the Crazy PSU, 1,535 acres within the disturbance boundary would occur within the habitat conditions identified in Table 190 for Alternative 3. Not all proposed clearing acres affect the cavity habitat PPL due to their location within a previously managed area. The effect of the vegetative clearing to the PPL in Alternative 3 is similar to Alternative 2 with a 1.0 percent reduction from 73.2 to 72.2 percent. Also, old growth and untreated stands would continue to be found within a majority of the PSU (69.2 percent) and provide a 100 percent snag level. Therefore, the cavity habitat PPL would remain well above the 40 percent level recommended in the KFP for upland habitats. Alternative 3 would impact 195 acres of riparian habitat on National Forest System lands. This is a reduction of 2.4 percent of riparian habitat available within the Crazy PSU and is minor at the PSU scale. Also, implementation of the agencies' Wetland and Mitigation Plan and the KFP's riparian standards and guidelines, as amended by the INFS, would minimize impacts on snag habitat in riparian areas on National Forest System lands. It is expected that this would result in meeting the riparian standard for snag levels (60 percent) within the PSU.

In comparison to Alternative 2, Alternative 3 would result in fewer acres that would be disturbed by clearing activities. This includes fewer acres being disturbed within riparian habitat and old growth and untreated stands. This includes 200 more acres of old growth and untreated stands that would be maintained with a 100 percent snag level in the vicinity of the mine for wildlife use. In addition, implementation of project design features would help to maintain or improve cavity habitat within the disturbance area. Also, mitigation plans, including the Vegetation Removal and Disposition Plan (discussed in section 2.5.2.5.2), call for the designation of 797 acres of effective or replacement old growth on National Forest System lands and that snags would be left in disturbance areas unless required to be removed for safety reasons. Therefore, the snag level would not be 0 percent on all cleared acres and at least portions of the disturbance areas may provide for some use by wildlife species both during mining operations and following reclamation. Effects of reduced cavity habitat with the Crazy PSU would be less in Alternative 3 compared to Alternative 2.

Alternative 3 would result in the loss of all down wood on 1,535 acres on National Forest System land in the Crazy PSU. This estimated reduction of down woody material would be minor as it would occur on 2.5 percent of the timbered lands within the PSU (Table 190). The effect to the availability of down wood from proposed vegetation clearing would be less than Alternative 2 by 1.2 percent. Also, estimated effects to down wood would be minimized in Alternative 3 through implementation of the Vegetation Removal and Disposition Plan developed for agencies' alternatives discussed in section 2.5.2.5.2. Down wood levels, on average, is expected to exceed KFP standards within the Crazy PSU for dependent wildlife species.

Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

The types of activities proposed under this alternative are similar to Alternatives 2 and 3. Similar facility and road construction activities would occur, but there are no LAD sites associated with Alternative 4 and the tailings impoundment has been modified from Alternative 2 to avoid RHCAs and old growth habitat. The disturbance area around the Little Cherry Creek Tailings

Impoundment Site would be 310 acres smaller than the Little Cherry Creek impoundment disturbance area proposed in Alternative 2.

Within the Crazy PSU, 1,634 acres within the disturbance boundary would occur within the habitat conditions identified in Table 190 in Alternative 4. Not all proposed clearing acres affect the cavity habitat PPL due to their location within a previously managed area. The effect of the vegetative clearing to the PPL in Alternative 4 would be similar to Alternatives 2 and 3 with a 0.9 percent reduction from 73.2 to 72.3 percent. Also, old growth and untreated stands would continue to be found within a majority of the PSU (69.3 percent) and provide a 100 percent snag level. Therefore, the cavity habitat PPL would remain well above the 40 percent level recommended in the KFP for upland habitats. Alternative 4 would impact 206 acres of riparian habitat on National Forest System lands. This is a reduction of 2.5 percent of riparian habitat available within the Crazy PSU and is minor at the PSU scale. Also, implementation of the agencies' Wetland and Mitigation Plan and the KNF's riparian standards and guidelines, as amended by the INFS, would minimize impacts on snag habitat in riparian areas on National Forest System lands. It is expected that this would result in meeting the riparian standard for snag levels (60 percent) within the PSU.

In comparison to Alternatives 2 and 3, Alternative 4 would result in a moderate reduction in cavity habitat acres due to proposed clearing activities. This includes fewer acres being disturbed within riparian habitat and old growth and untreated stands than Alternative 2 and is similar to Alternative 3. Approximately 204 acres of old growth and untreated stands would be maintained with a 100 percent snag level in the vicinity of the mine for wildlife use. In addition, implementation of project design features would help to maintain or improve cavity habitat within the disturbance area. Also, mitigation plans, including the Vegetation Removal and Disposition Plan (discussed in section 2.5.2.5.2), call for the designation of 828 acres of effective or replacement old growth on National Forest System lands and that snags would be left in disturbance areas, unless required to be removed for safety reasons (see section 2.5.7.4.4, *Key Habitats*). Therefore, the snag level would not be 0 percent on all cleared acres and at least portions of the disturbance areas could provide for some use by wildlife species both during mining operations and following reclamation. Effects of reduced cavity habitat with the Crazy PSU are reduced in Alternative 4 compared to Alternative 2 and would result in a greater designation of old growth habitat than Alternative 3.

Alternative 4 would result in the loss of all down wood on 1,634 acres on National Forest System land in the Crazy PSU. This estimated reduction of down woody debris would be minor as it would occur on 2.7 percent of the timbered lands within the PSU (Table 190). The effect to the availability of down wood from proposed vegetation clearing would be less than Alternative 2 by 1.0 percent and similar to Alternative 3. Also, estimated effects to down wood would be minimized in Alternative 4 through implementation of the Vegetation Removal and Disposition Plan developed for agencies' alternatives discussed in section 2.5.2.5.2. Down wood levels, on average, is expected to exceed KFP standards within the Crazy PSU for dependent wildlife species.

Alternative A – No Transmission Line

No direct effects from federal actions would occur. The No Transmission Line Alternative would maintain existing vegetative condition on the landscape and wildlife use of cavity and down wood habitat would continue at current levels. Although past timber harvests and other vegetation management treatments often resulted in a decrease in the amount of both habitats available, especially in some existing regeneration harvest units, both District and Forest level monitoring indicates that current levels meet KFP standards. Current down wood levels are generally considered to exceed historical levels due to longer fire return intervals within stands (Graham *et al*. 1994, Brown *et al*. 2003). The addition or loss of snags would depend on other factors, such as firewood cutting, wind events, natural attrition, or wildfire. The level of impact from these factors cannot be calculated due to the high uncertainty in predicting occurrence and intensity levels. Similarly, this alternative would not change the current condition or availability of down wood within the PSUs.

Effects Common to All Transmission Line Action Alternatives

The Montanore Project has four transmission line action alternatives: MMC's Proposed Transmission Line (Alternative B), Modified North Miller Creek (Alternative C-R), Miller Creek (Alternative D-R), and West Fisher Creek (Alternative E-R). In general, vegetation would be cleared from access roads, pulling and tensioning sites, substation and loop line, and within the transmission line clearing area for all action alternatives. For all but Alternative B, alternative design and topography would help maintain some snags within the identified disturbance areas. For example, snags located outside of the transmission lines right-of-way would only be removed if deemed a safety hazard. Harvest would not occur and trees would be maintained in portions of the clearing area, such as within high spans across valleys. New roads would not be open to the public; therefore, areas adjacent to new transmission line access roads would not likely have reduced snag levels from firewood gathering. Also, impacts on cavity habitat in riparian areas in the agencies' alternatives would be minimized through implementation of KFP riparian standards and guidelines, as amended by the INFS (USDA Forest Service 1995) on National Forest System lands as well as the Environmental Specifications (Appendix D) on all lands impacted by the transmission lines in the agencies' alternatives. It is expected that this would result in meeting the riparian standard for snag levels (60 percent) on National Forest System lands within the PSUs.

Transmission line clearing activities on National Forest System lands would occur within the Crazy and Silverfish PSUs. Clearing within old growth and untreated stands would have the most potential impact on the existing cavity habitat PPL and down wood debris levels. Disturbance would also occur within riparian habitat (Table 194). However, due to the relatively few acres that would be cleared at the PSU scale within these habitat conditions and that a portion of the acres occur within stands that already have a reduced snag level, the effect of this clearing activity to the cavity habitat PPL and down wood levels would be negligible. Also, both old growth and untreated forest conditions would continue to comprise the majority of the PSUs (Table 192) and these moist habitats provide snag levels on the KNF in the range of 6.3 to 17.1 per acre (Bollenbacher *et al*. 2009). Therefore, the cavity habitat PPL would remain well above the 40 percent level recommended in the KFP for upland habitats under all of the transmission line action alternatives. Down woody debris would be maintained in portions of the clearing area, such as within high spans across valleys. Also, impacts on down wood habitat in riparian areas in the agencies' alternatives would be minimized through implementation of KFP riparian standards and guidelines, as amended by the INFS (USDA Forest Service 1995) on National Forest System lands as well as the Environmental Specifications (Appendix D) on all lands impacted by the agencies' transmission line alternatives. Down wood levels, on average, is expected to exceed KFP standards within the Crazy and Silverfish PSUs for dependent wildlife species based on: 1) the predominant habitat type within the disturbance area, 2) the amount of old growth and untreated stands within the PSU, 3) the existing level of down wood as supported by District surveys, and 4) because current down woody debris levels are generally considered to exceed historical levels due longer fire return intervals within stands (Graham *et al*. 1994, Brown *et al*. 2003).

Clearing activities would also occur on private and State lands within the Silverfish PSU as well as the McElk and Riverview PSUs to the east. The majority of the private land that would be disturbed by the action alternatives, including the Sedlak Park Substation and loop line, is heavily roaded and has been logged in the past 20 to 30 years, and likely provides less cavity habitat than National Forest System lands. The amount of land on which these clearing acres would occur are negligible compared to the amount of private and State lands within the PSUs, for both upland and riparian habitats. Also, because of the low snag and down wood debris levels expected to currently exist on these lands, this reduction in cavity and down wood habitats on private and State lands, including the Sedlak Park Substation and loop line, would be negligible compared to the existing condition.

The subsections below describe the differences between the proposed action alternatives. The differences include total acres impacted, division of acres on National Forest System versus private and State lands, the types of habitat condition the clearing would occur in, and additional design features and/or mitigation plan measures that would be implemented. Table 192 summarizes the impacts of the transmission line alternatives on National Forest System lands and the change to the cavity habitat PPL within the Crazy and Silverfish PSUs. Impacts from all alternatives to habitat condition acres, proportion of National Forest System lands, and PPL have been calculated and are available in the project record. Table 193 displays the impacts of the alternatives on private and State lands within the Crazy, Silverfish, McElk, and Riverview PSUs. The impacts considered on private and State lands include the clearing areas associated with the transmission lines, and consider this impact in context with the amount of private and State lands available within the PSU.

Table 192. Impacts on Snag Habitat and Potential Population Level on National Forest System Lands in the Crazy and Silverfish PSUs by Transmission Line Alternative.

Activity	PSU	[A] No Transmission Line/Existing Conditions	[B] MMC's Proposed North Miller Creek Alternative	[C-R] Modified North Miller Creek Alternative	[D-R] Miller Creek Alternative	[E-R] West Fisher Creek Alternative
Total Clearing Acres	Crazy	0	114	73	73	73
	Silverfish	0	69	138	125	140
Acres Within Old Growth (% PPL)[1]	Crazy	0	24 (-0.1)	0 (0)	0 (0)	0 (0)
	Silverfish	0	8 (0)	18 (-0.1)	4 (0)	0 (0)
Acres Within Untreated Forest (% PPL)[1]	Crazy	0	39 (0)	36 (0)	26 (0)	26 (0)
	Silverfish	0	33 (0)	68 (-0.1)	37 (0)	9 (0)
Acres Within Past Harvest/ Road (% PPL)[1]	Crazy	0	51 (0)	37 (0)	47 (0)	47 (0)
	Silverfish	0	28 (0)	52 (0)	84 (0)	131 (-0.1)[2]
PPL (% Change)	Crazy	73.2	73.1 (-0.1)	73.2 (0)	73.2 (0)	73.2 (0)
	Silverfish	90.5	90.5 (0)	90.3 (-0.2)	90.5 (0)	90.4 (-0.1)

[1] % PPL: represents the percent change in the PPL from the existing condition.
[2] The one-tenth percent change due to clearing acres occurred within past partial cut forest condition.

Table 193. Private and State Lands within the PSU Impacted by the Transmission Line Alternative's Clearing Areas.

PSU	[B] MMC's Proposed North Miller Creek Alternative (Acres %)	[C-R] Modified North Miller Creek Alternative (Acres %)	[D-R] Miller Creek Alternative (Acres %)	[E-R] West Fisher Creek Alternative (Acres %)
Crazy	0 (0%)	0 (0%)	0 (0%)	0 (0%)
Silverfish	39 (0.4%)	35 (0.4%)	35 (0.4%)	86 (0.9%)
McElk	55 (0.1%)	72 (0.2%)	72 (0.2%)	72 (0.2%)
Riverview	39 (0%)	6 (0%)	6 (0%)	6 (0%)

Table 194. Riparian Habitat on National Forest System and Private and State Lands Impacted by Transmission Line Alternative.

PSU	Land Ownership	[B] MMC's Proposed North Miller Creek Alternative (Acres %)	[C-R] Modified North Miller Creek Alternative (Acres %)	[D-R] Miller Creek Alternative (Acres %)	[E-R] West Fisher Creek Alternative (Acres %)
Crazy	NFS	20 (0.2%)	8 (0.1%)	26 (0.3%)	26 (0.3%)
	Private/State	0 (0%)	0 (0%)	0 (0%)	0 (0%)
Silverfish	NFS	9 (0.1%)	16 (0.2%)	9 (0.1%)	6 (0.1%)
	Private/State	15 (0.8%)	6 (0.3%)	6 (0.3%)	21 (1.2%)
McElk	NFS	0 (0%)	0 (0%)	0 (0%)	0 (0%)
	Private/State	2 (0%)	5 (0.1%)	5 (0.1%)	5 (0.1%)
Riverview	NFS	0 (0%)	0 (0%)	0 (0%)	0 (0%)
	Private/State	18 (0.2%)	2 (0%)	2 (0%)	2 (0%)

NFS = National Forest System.
Percents shown represent percent of available riparian habitat in entire PSU.

Alternative B – MMC Proposed Transmission Line

This transmission line alternative would be 16.4 miles long with an associated clearing area of 150 feet. Alternative B would clear 153 acres on National Forest System lands, including 114 and 69 acres in the Crazy and Silverfish PSUs, respectively (Table 192). This includes impacts to 32 acres of old growth and 72 acres of untreated stands and these two habitat conditions would continue to comprise the majority of the PSUs (Table 189). This also includes disturbance to riparian habitat, including 20 acres within the Crazy PSU and 9 acres within the Silverfish PSU. This would amount to 0.1 to 0.2 percent of total riparian habitat available within the PSU and would be negligible at this scale. Also, there would be no effect to the cavity habitat PPLs. Down wood habitat would be reduced on these 153 acres of National Forest System lands as well. Effects to the down wood habitat level within the Crazy and Silverfish PSUs would be negligible based on the existing high levels and the availability of old growth and untreated forest habitats.

An additional 133 acres of clearing would occur on private and State lands (Figure 78) within the impacted PSUs. As described above, the existing snag level is already reduced on much of these lands and the proposed clearing acres would small compared the amount of land available within the PSU; effects would be negligible. Disturbance to riparian habitats would occur on 2, 18, and 15 acres within the McElk, Riverview, and Silverfish PSUs, which account for ≤0.8 percent of the private and State lands. Similarly, removal of down woody debris would occur on ≤0.4 percent of the private and State lands within the PSUs. In addition, the proposed clearings would not be expected to reduce the available wood debris level to an extent different from the existing low level condition found within these areas. Effects would be negligible on private and State lands at the PSU scale.

Alternative C-R – Modified North Miller Creek Transmission Line Alternative

The location of this transmission line alignment was intended to increase the acreage located on National Forest System lands versus private and State lands. This transmission line is the shortest of all alternatives and would be 13.1 miles long with an associated clearing area of 200 feet due to the use of wooden H-frame structures that are wider than the steel monopoles used in Alternative B. Alternative C-R would clear 211 acres on National Forest System lands, including 73 and 138 acres in the Crazy and Silverfish PSUs, respectively (Table 192). This would amount to 0 and 0.2 percent of the PSUs, respectively, with negligible effects to the cavity habitat PPLs. Clearing would impact fewer acres of old growth, totaling only 18 acres of old growth found within the Silverfish PSU, but more acres of untreated stands at about 104 acres between the two PSUs. Additionally, the goal of the Vegetation Removal and Disposition Plan would be to reduce the amount of vegetation clearing associated with the lines. Alternative C-R would disturb 8 and 16 acres (0.1 to 0.2 percent) of riparian habitat of National Forest System lands in the Crazy and Silverfish PSU, respectively, and would be negligible at the PSU scale.

Alternative design and topography would help maintain some snags within the clearing and disturbance areas. In addition, the mitigation plan for this alternative calls for the designation of 29 acres of effective or replacement old growth on National Forest System lands and that snags would be left in clearing area unless required to be removed for safety reasons. Although slightly more acres of clearing would occur on National Forest System lands with this alternative compared to Alternative B, the amount of acres would still be very small compared to cavity habitat available within the PSU and Alternative C-R would maintain the cavity habitat PPL well above the 40 percent level recommended in the KFP for upland habitats. Also, this alternative would reduce the impact on habitat conditions that provide 100 percent snag level through a reduction in the amount of clearing occurring within old growth habitat and the designation of additional old growth acres as well as the retention of snags that do not pose a safety hazard within the clearing acres. Fewer acres would be cleared in riparian habitats with this alternative than Alternative B. Therefore, the effects of the vegetation clearing with the Crazy and Silverfish PSUs would be reduced in Alternative C-R compared to Alternative B.

Approximately 113 acres of clearings would occur on State and private lands (Figure 78) within the impacted PSUs. This is a reduction of 20 acres that would occur on State and private lands than in Alternative B. Fewer acres would also be cleared within riparian habitats (13 compared to 35 acres). Overall, the effects would be the same to Alternative B and negligible as these lands already have reduced cavity habitat levels and activity would occur on ≤0.4 percent of private and State lands within each PSU.

Alternative C-R could impact the amount of down wood on 211 acres on National Forest System land in the Crazy and Silverfish PSUs. However, in contrast to Alternative B, alternative design and topography would help maintain some down wood debris within the identified clearing areas. In addition, the mitigation plan for this alternative calls for leaving up to 30 tons per acre of coarse woody debris within clearing area (Table 37). Therefore, potential effects to down wood debris under this alternative are negligible, reduced compared to Alternative B, and would maintain levels appropriate for the site for wildlife use.

As described for cavity habitat, potential impacts to down woody debris would occur on ≤0.4 percent of the private and State lands within the PSUs where it is expected that reduced levels of down wood material already exist. The mitigation plan would retain up to 30 tons per acres of coarse woody debris within these disturbance areas that could be acquired upon removal of the trees. Therefore, there is the potential for improvement in the down woody debris levels on State and private lands under this alternative and is an improvement compared to Alternative B.

Alternative D-R – Miller Creek Transmission Line Alternative

Similar to Alternative C-R, the location of this transmission line would increase the acreage located on National Forest System lands versus private and State lands but reduce the amount of vegetation clearing associated with the line through implementation of the Vegetation Removal and Disposition Plan. This transmission line alternative would have the same clearing area of 200 feet as Alternative C-R, but would be slightly longer at 13.7 miles. Alternative D-R would clear 198 acres on National Forest System lands, including 73 and 125 acres in the Crazy and Silverfish PSUs, respectively (Table 192). There would be no effect to the PPL. Clearing would impact fewer acres of old growth and untreated forest than either Alternatives B or C-R, totaling only 4 acres of old growth within the Silverfish PSU, and 63 acres of untreated stands split between the two PSUs. Within the Crazy PSU, more riparian habitat would be impacted with this alternative than either Alternatives B or C-R with 26 acres proposed for clearing. This alternative proposes the clearing of 9 acres of riparian habitat in the Silverfish PSU. This is the same as Alternative B and slightly less than Alternative C-R and the effects would be negligible.

Similar to Alternative C-R, alternative design and topography would help maintain some snags within the clearing and other disturbance areas. In addition, the mitigation plan for this alternative calls for the designation of 12 acres of effective or replacement old growth on National Forest System lands and that snags would be left in clearing area unless required to be removed for safety reasons (Table 37). Although slightly more acres of clearing would occur on National Forest System lands with this alternative compared to Alternative B, the amount of acres is still very small compared to cavity habitat available within the PSU and Alternative D-R would maintain the cavity habitat PPL well above the 40 percent level recommended in the KFP for upland habitats and continue to meet the 60 percent level within the riparian habitats. Also, this alternative reduces the impact on habitat conditions that provide 100 percent snag level through a reduction in the amount of clearing occurring within old growth habitat and the designation of additional old growth acres as well as the retention of snags that do not pose a safety hazard within the clearing acres. Therefore, the effects of the vegetation clearing with the Crazy and Silverfish PSUs are reduced in Alternative D-R compared to Alternatives B and C-R.

Approximately 113 acres of clearings would occur on State and private lands (Figure 78) within the impacted PSUs. This is a reduction of 20 acres that would occur on State and private lands than in Alternative B and is the same as Alternative C-R. Impacts to riparian habitat would be the same as Alternative C-R (13 acres) and less than Alternative B. Overall, the effects would be the same as Alternative C-R and negligible as these lands already have reduced cavity habitat levels and activity would occur on ≤0.4 percent of each PSU.

Alternative D-R would impact the amount of down wood on 198 acres on National Forest System land in the Crazy and Silverfish PSUs. However, similar to Alternative C-R, alternative design and topography would help maintain some down wood debris within the identified clearing areas. In addition, as for Alternative C-R the mitigation plan for this alternative calls for leaving up to 30 tons per acre of coarse woody debris within clearing area (Table 37). Therefore, potential effects to down wood debris under this alternative are reduced compared to Alternative B and similar to Alternative C-R, and would maintain levels appropriate for the site for wildlife use.

As described for cavity habitat, potential impacts to down woody debris would occur on ≤0.4 percent of the private and State lands within the PSUs where it is expected that reduced levels of down wood material already exist. The mitigation plan would retain up to 30 tons per acres of coarse woody debris within these clearing areas, assuming this level of debris is available for retention. Therefore, there is the potential for improvement in the down woody debris levels on State and private lands under this alternative and is an improvement compared to Alternative B and the same as Alternative C-R.

Alternative E-R – West Fisher Creek Transmission Line Alternative

Similar to Alternatives C-R and D-R, the clearing for this transmission line would reduce the amount of vegetation cleared through implementation of the Vegetation Removal and Disposition Plan. However, the location of the transmission line would result in the most acres being impacted by clearing activities, both on National Forest System and private and State lands. This transmission line would have a mixed-width disturbance area depending on whether the section of line consisted of wooden H-frame structures (200-foot clearing area and majority of the line) or wooden monopoles (150-foot clearing area). The total length is 15.1 miles which is intermediate between Alternatives B and C-R. Alternative E-R would clear about 213 acres on National Forest System lands, including 73 and 140 acres in the Crazy and Silverfish PSUs, respectively. This would amount to 0 and 0.1 percent and would be negligible at the PSU scale (Table 192). Clearing would not impact old growth with this alternative as compared to all other alternatives. This alternative would also impact the fewest acres of untreated forest compared to the other three action alternatives, totaling 35 acres between the two PSUs. This alternative would clear 26 acres within riparian habitats in the Crazy PSU, similar to Alternative D-R, but the fewest acres (6 acres) within the Silverfish PSU compared to all other alternatives and effects would be negligible.

Similar to Alternative C-R, alternative design and topography would help maintain some snags within the identified disturbance areas. In addition, the mitigation plan for this alternative calls for the designation of 6 acres of effective or replacement old growth on National Forest System lands and that snags would be left in clearing area unless required to be removed for safety reasons (Table 37). Although slightly more acres of clearing would occur on National Forest System lands with this alternative compared to the other action alternatives, the amount of acres would be still very small compared to cavity habitat available within the PSU and Alternative E-R would maintain the cavity habitat PPL well above the 40 percent level recommended in the KFP for upland habitats and continue to meet the 60 percent level within the riparian habitats. Also, this alternative would reduce the impact on habitat conditions that provide 100 percent snag level through the elimination of clearing within old growth habitat and the reduction of clearing within untreated forest, the designation of additional old growth acres, and the retention of snags that do not pose a safety hazard within the clearing acres. Therefore, the effects of the vegetation clearing under this alternative would be similar to Alternative C-R with respect to the amount of clearing that would occur but reduced effects within old growth and untreated forest that provide the highest snag levels compared all of the other action alternatives. More total acre would be cleared with this alternative than Alternative D-R, but more would occur within previously disturbed with similar or slightly less effects to old growth and untreated stands.

Approximately 164 acres of clearings would occur on State and private lands (Figure 78) within the impacted PSUs. This is an increase of 31 and 51 acres than would occur on State and private lands with Alternative B and Alternatives C-R and D-R, respectively. Impacts to riparian habitat ranges between 2 and 21 acres with this alternative, totaling 29 acres on private and State lands. This is more acres than Alternatives C-R and D-R but less than Alternative B. Overall, the effects would be similar to the other action alternatives and negligible as these lands already have reduced cavity habitat levels and activity would occur on ≤0.9 percent of each PSU.

Alternative E-R could impact the amount of down wood on about 213 acres on National Forest System land in the Crazy and Silverfish PSUs. However, similar to Alternative B, alternative design and topography would help maintain some down wood debris within the identified clearing areas. In addition, as for Alternatives C-R and D-R the mitigation plan for this alternative calls for leaving up to 30 tons per acre of coarse woody debris within clearing area (Table 37). Therefore, potential effects to down wood debris under this alternative are negligible, reduced compared to Alternative B and similar to Alternatives C-R and D-R, and would maintain levels appropriate for the site for wildlife use.

As described for cavity habitat, potential impacts to down woody debris would occur on ≤0.1 percent of the private and State lands within the PSUs where it is expected that reduced levels of down wood material already exist. The mitigation plan would retain up to 30 tons per acres of coarse woody debris within these clearing areas, assuming this level of debris is available for retention. Therefore, there would be no effect to down wood habitat on State and private lands under this alternative and is an improvement compared to Alternative B and the same as Alternatives C-R and D-R.

Combined Mine-Transmission Line Effects

When considering the mine and transmission lines in combination, only the Crazy PSU could have increased impacts as it is the only PSU where both mine facilities and the transmission line would be located. Some overlap of impact acres would occur where the transmission lines terminated at the plant site. These overlapping acreages are small, but were not double counted when assessing the combined acres in Table 195. Within the Crazy PSU, transmission lines D-R and E-R alignments would be the same and combined effects with the mine alternatives would be the same; therefore, these transmission line alternatives are shown in the same column in Table 195. For the other PSUs, the “combined effects” would be the same as those described above under the transmission line alternatives.

Table 195. Impacts of Combined Mine and Transmission Line Alternative on Cavity Habitat Population Level and Riparian Habitat on National Forest System Land in the Crazy PSU.

Activity	[1A] Existing Condition	[2] MMC's Proposed Mine	[3] Agency Mitigated Poorman Impoundment Alternative		[4] Agency Mitigated Little Cherry Creek Impoundment Alternative	
		[B]	[C-R]	[D-R] and [E-R]	[C-R]	[D-R] and [E-R]
Cavity Habitat Population Level						
Total Clearing Acres	0	2,378	1,605	1,605	1,704	1,704
Acres Within Old Growth (% PPL)[1]	0	319 (-0.5)	138 (-0.3)	138 (-0.3)	159 (-0.3)	159 (-0.3)
Acres Within Untreated Forest (% PPL)[1]	0	380 (-0.6)	342 (-0.5)	332 (-0.5)	317 (-0.5)	307 (-0.5)
Acres Within Partial Cut Forest (% PPL)[1]	0	199 (-0.3)	193 (-0.2)	191 (-0.2)	110 (-0.2)	108 (-0.2)
Acres Within Past Regeneration Harvest/Roads (% PPL)[1]	0	1,480 (0)	932 (0)	944 (0)	1,118 (0)	1,130 (0)
PPL (% Change)	73.2	71.8 (-1.4)	72.2 (-1.0)	72.2 (-1.0)	72.2 (-1.0)	72.2 (-1.0)
Riparian Habitat						
Riparian Habitat Acres (% PSU)	0	252 (3.1)	203 (2.5)	221 (2.7)	214 (2.6)	232 (2.8)

[1] % PPL: represents the percent change to the PPL from the existing condition.

Relative to other action alternatives, combined Alternative 2B would result in the greatest impacts on the availability of snags. This alternative would result in the disturbance/clearing of the most total acres, 2,378 acres, as well as impacting the most old growth and untreated forest (319 and 380 acres, respectively). Also, this alternative results in the disturbance of 252 acres (3.1 percent) of riparian habitat, which is more than any of the other alternatives. However, this combined reduction in acres only results in a negligible decrease in the cavity habitat PPL compared to the mine alternative alone and the PPL would be 71.8 percent in the Crazy PSU. As the numbers in Table 195 indicate, there is very little difference between Alternatives C-R and D-R/E-R when in combination within the respective mine alternative and only considering National Forest System lands. Alternative 3 combinations would have the least potential impact on cavity habitat (1,605 acres), acres occurring within an old growth condition (138 acres), and range of acres occurring in riparian habitat (203 to 221 acres). Alternative 4 combinations would result in intermediate impacts, although more similar to Alternative 3. This combination of alternatives would impact 1,704 acres in total with 159 occurring in old growth and 214 to 232 acres within riparian habitat. These alternatives have additional mitigation plans in place that would retain snags in the disturbance/clearing areas that would not occur under combined Alternative 2B. Similar to combined Alternative 2B, the proposed combined reductions in the PPL are negligible compared to the mine Alternatives 3 and 4 alone and would remain at 72.2 percent. In all combined action alternatives, the PPL would remain well above the 40 percent recommended in the KFP for upland habitat and continue to meet the 60 percent standard for riparian habitat across the PSU.

Combined effects for the potential reduction of down wood debris would be similar to cavity habitat. The Alternative 3 combinations would have the least impact on down wood habitat as it proposes the fewest disturbance/clearing acres, followed by Alternative 4 combinations. In addition, the mitigation plan for the agencies' alternatives propose to leave up to 30 tons per acre of coarse woody debris under the transmission lines to maintain down wood habitat.

Cumulative Effects

The Affected Environment/Existing Condition section describes the past and present factors contributing to the existing cavity and down wood habitat conditions within the analysis area. This cumulative effects section summarizes the past actions as well as further describes ongoing and other reasonably foreseeable contributions potentially impacting cavity and down wood habitats. As described under the section "Analysis Areas and Methods," the PSU was chosen as the appropriate scale for cavity and down wood habitat cumulative effects analysis as this size is sufficient to cover home range sizes of species associated with cavity and down wood habitat as well as to be able to determine the effects of proposed management activities.

Past Actions

Past actions, including detailed descriptions of previous vegetation and road management activities, are described in section 3.2, *Past and Current Actions*, shown on Figure 50, and listed in Appendix E. Cavity and down wood habitats are affected by various activities both directly and indirectly. Therefore, changes in the availability of cavity habitat, as compared to the 40 and 60 percent standards, and down wood habitat are the measure of effects. The Affected Environment section of this analysis summarizes the existing condition and Table 190 and Table 192 reflect the changes to the upland snag level and PPL under the mine and transmission line alternatives, respectively. Table 191 displays the impacts to riparian habitats. Effects to down wood habitat were more qualitative in nature. Harvest and other vegetation management have occurred in the analysis area since the 1950s. Before the 1990s, these activities resulted directly in the loss of snags as well as indirectly through reductions in trees that would have become snags in the future. Similarly, past vegetation management often resulted in the direct loss of down woody debris as well as indirectly through reductions in trees and snags that would have become down woody materials in the future. Road construction and the amount of road open to public motorized use also reduced the availability of snags and down wood due to firewood collection. In unmanaged areas, natural disturbances such as wildfire would have resulted in the development of clusters of snags. Fires would have both reduced down woody debris as well as the development of snags that would come down in the future. In contrast, fire suppression since the early 1900s has altered stand structure resulting in reduced creation of snags and development of future snags. It has also resulted in the large accumulations of small down wood debris that does not persist on the landscape nor are as beneficial to wildlife. Since the 1990s, application of KFP standards has resulted in the better retention of snags, snag replacement trees, and existing and future down wood materials. There has been more reliance on intermediate harvest that leaves more trees that would become snags and down wood in the future. Also, there has been a reduction in roads available for public motorized use, which has affected the location and amount of snag habitat available for firewood gathering. Application of these standards and management trends has since provided better protection and maintenance of cavity and down wood habitat.

The No Action Alternatives (Alternatives 1 and A)

No direct effects from federal actions would occur; therefore, these alternatives would not contribute to cumulative losses of snags and down wood, and would not contribute to cumulative effects on cavity and down wood habitats. Implementation of these alternatives would maintain existing vegetative condition on the landscape and wildlife use of cavity and down wood habitat would continue at current levels. Although past timber harvests and other vegetation management treatments resulted in a decrease in the amount of both habitats available in some existing regeneration harvest units, both District and Forest level monitoring indicates that current levels meet KFP standards. Also, current down wood levels are generally considered to exceed historical levels due to longer fire return intervals within stands (Graham *et al*. 1994, Brown *et al*. 2003). The addition or loss of snags would depend on other factors, such as firewood cutting, wind events, natural attrition, or wildfire.

Mine Alternatives (2, 3, 4), Transmission Line Alternatives (B, C-R, D-R, E-R), and Combined Mine-Transmission Line Alternatives

Ongoing and Reasonably Foreseeable Actions

Reasonably foreseeable actions include those federal, state, or private activities that are ongoing or scheduled to occur within the next five years, independent of this federal action. Section 3.2, *Past and Current Actions*, and Appendix E identify those current and foreseeable actions in the analysis area that were determined to be appropriate for inclusion in the analysis of environmental effects. As described above, cavity and down wood habitat has been reduced due to past actions that have occurred within the analysis area. However, abundant snags and down wood debris occur throughout the analysis area due the habitat types and moist environments found here. Changes in harvest methods and retention and protection of snags and down wood materials in recent years have maintained/created higher quality cavity and down wood habitat throughout the analysis area PSUs.

One active timber sale, Miller-West Fisher, occurs within the Silverfish PSU. The project includes commercial timber harvest, which was included in the existing condition PPL. Only the transmission line alternatives would occur within this PSU and the cumulative impact on the cavity habitat PPL would be a 0 to 0.2 percent reduction. This reduction would be negligible at the PSU scale and would maintain the cavity habitat PPL well above the 40 percent standard. Miller-West Fisher would adhere to riparian standards and there would be no cumulative effect to the 60 percent riparian standard. Prescribed fire units and post-harvest burning could kill or injure some of the live trees within the units, especially those harvest units with more western redcedar left, and create more snags. Cumulatively, the impacts of the two projects to snag level in the PSU would be negligible as only relatively few acres would be cleared under the transmission line alternatives, the agencies' alternatives would retain existing snags where possible to meet KFP recommendations, and the reduction to the high snag PPL within the PSU would be negligible. Project design would require that the down wood materials be left as appropriate for the habitat type; therefore, there would be no cumulative reduction in down wood on National Forest System lands.

The Coyote Improvement vegetation management project is in the planning stages and would take place within the Crazy PSU. The project would harvest 240 acres to increase stand resiliency to mountain pine beetles. If this harvest occurs within currently untreated forest stands, at most the PPL would be reduced by 0.4 percent within the PSU. In addition to the proposed activities, this would still result in a minor reduction in the PPL in the Crazy PSU and maintain a very high PPL above 71 percent. Also, the project would meet riparian standards. Project design would require that the down wood materials be left as appropriate for the habitat type; therefore, there would be no cumulative reduction in down wood on National Forest System lands.

Increased use of public lands is likely with population growth and development, but use is expected to be gradual and focused on areas along or near roads open to motorized traffic. Activities include firewood cutting which removes snags and down wood. Loss would be limited to individual trees and logs and to areas within about 150 to 200 feet of open roads and has been accounted for in available snag habitat. Also, the Montanore Project proposes no increase in the amount of roads open for public motorized use. However, new clearings within viewing distance of the open roads may make existing snags more visible for cutting. Therefore, cumulatively there would be a negligible increase in the expected loss of snags and down wood due to proposed activities and firewood gathering within the analysis area.

Development of private land within the analysis area likely resulted in the loss of both existing and future snags, including in riparian areas such as along the Fisher River. Also, as discussed above under "Environmental Consequences" much of the State and private lands within the project PSUs have been harvested within the past 20 to 30 years and already have a reduced cavity habitat PPL and down wood level. Further development would not be expected to reduce these habitats compared to the existing condition. In addition, high levels of both habitats currently exist on adjacent National Forest System lands that would continue to provide habitat for cavity and down wood dependent species.

Following implementation of any of the action alternatives and reasonably foreseeable Forest Service projects, the primary cavity excavator PPL on National Forest System lands would remain at ≥ 71 percent. Only the Crazy PSU would experience a 1 percent decrease in the PPL due to proposed mine and transmission line alternatives. The remaining PSUs would experience negligible to no effects to the PPL on National Forest System lands. This level of snag habitat is expected to provide for cavity habitat associated species PPL well above 40 percent, which is thought to be the minimum needed to maintain self-sustaining populations of snag-dependent wildlife (Thomas 1979). Additionally, due to the ongoing and future predicted bark beetle epidemics and fire, it is anticipated that the density of snags is increasing in all diameter classes over time (Bollenbacher *et al*. 2009). Impacts to riparian habitats would be negligible and expected to maintain cavity habitat PPL above 60 percent across the PSUs. Productive growing conditions on impacted National Forest System lands have resulted in high existing levels of down wood materials. Proposed clearings would result in negligible reductions at the PSU scale. Also, mitigation plans under the agencies' proposed alternatives would reduce this potential reduction level. Cumulatively, when proposed activities and all past, present, and reasonably foreseeable activities are considered, habitat on federal lands is considered sufficient to provide cavity and down wood habitat to cavity and down wood dependent species within the impacted PSUs. Proposed activities on State and private lands are expected to have negligible cumulative effects due to the reduced availability of these habitat types currently existing on these lands, the small amount of acres that would be cleared for the transmission line alternatives, and coarse woody would be retained up to 30 tons per acre under the agencies' alternatives.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8. In the proposed action, MMC did not propose to implement feasible measures to minimize effects on key habitats

or all practicable measures to maintain and protect wildlife habitat. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would comply with 36 CFR 228.8. The agencies' alternatives would incorporate additional feasible and practicable measures to minimize adverse environmental impacts on wildlife habitat that benefit key habitats, including leaving snags in disturbance and clearing areas unless required to be removed for safety reasons, leaving down wood on National Forest System and State lands minimizing effects on riparian areas and complying with all KFP riparian standards, and having a wetland mitigation plan more likely to replace lost wetland functions.

National Forest Management Act/Kootenai Forest Plan

The combined mine and transmission line action alternatives meet KFP guidelines and standards as they apply to cavity and down wood habitat on National Forest System land and include:

1. Forestwide Management Direction, KFP II-1 #8 – *Manage for sufficient snags and snag replacement trees to maintain viable populations of snag-dependent species.* Within the Crazy PSU, the combined mine and transmission line alternatives would reduce PPL by about 1 percent to 72 percent. The transmission line alternatives within the Silverfish PSU would have a negligible effect to the PPL, a maximum of a 0.2 percent decrease, and would maintain a PPL of 90 percent. Both PSUs would continue to provide a snag level higher than 40 percent within the analysis area. The transmission line clearings would not impact National Forest System lands within the McElk and Riverview PSUs. Impacts to riparian habitat are negligible at the PSU scale and these habitats would continue to meet the 60 percent standard within the PSUs.

2. Cavity Habitat standard in MAs 10, 11, 12, 15, 16, 17, and 18

    a. a. MA 10 – KFP III-39: *Existing cavity habitat will be retained.* The requirement to retain habitat in MA 10 would continue to be met because none of the disturbance associated with the action alternatives would occur in MA 10.

    b. MAs 11, 12, 15, 16, 17, and 18 – KFP III-44, 49, 65, 69, 75, and 80, respectively: *Cavity habitat will be maintained at 40 percent of maximum as described in Appendix 16, "Cavity Habitat Management Guidelines."* In all alternatives, the KFP cavity habitat standard (40 percent PPL) in MAs 11, 12, and 15 through 18 would be met. The total acres proposed for reduction are small compared to the high levels of old growth and untreated habitats that would continue to provide a 100 percent snag level within the Crazy and Silverfish PSUs and National Forest System lands would not be impacted within the McElk and Riverview PSUs. In addition, under the agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) snags would be left within the disturbance and/or clearing acres unless required to be removed for safety reasons and would newly designate old growth acres that would maintain the old growth characteristics.

3. Appendix 16 – *A 16-4: Minimum levels for cavity habitat retention should be applied on a drainage or compartment area basis at the following recommended levels: At least 40 percent of the potential capacity will be maintained throughout commercial forest lands and at least 60 percent of the potential will be maintained in riparian areas.* Within the Crazy and Silverfish PSUs, upland areas of National Forest System lands unaffected by the proposed combined mine and transmission line alternatives would exceed 40 percent

snag level as described in 2b above. In the agencies' alternatives, implementation of KNF riparian standards and guidelines, as amended by the INFS (USDA Forest Service 1995), and the Environmental Specifications would help minimize impacts on snag habitat in riparian areas within the proposed clearing and disturbance areas and would ensure the 60 percent level is being met in the PSUs.

The KFP has no standards for down wood habitat. It does contain the goal to maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species (II-1). Also, it provides guidelines in Appendix 16, Cavity Habitat Management (A-16-6) to leave logs greater than 12 inches in diameter (a few pieces or about 5-15 tons/acre) to provide cover and feeding sites for birds and small mammals. Given the wide range of habitats and different successional stages and associated amounts of downed wood that would continue to be available within the impacted PSUs, all combined mine and transmission line alternatives would be consistent with the KFP.

Statement of Findings

Based on the analysis for cavity habitat, analyzing snags as the primary substrate, habitat for cavity dependent species would be maintained at a minimum PPL of about 72 percent in the impacted PSUs. Although up to 2,378 acres would be impacted under combined Alternative 2B in the Crazy PSU, the majority would occur within stands that already have a reduced snag level due to prior treatment or use as a road. Also, the overall acres proposed for reduction are small compared to the high levels of old growth and untreated habitats that would continue to provide a 100 percent snag level within the PSU; fewer acres would be disturbed and cleared under the combined Alternatives 3 and 4. The transmission line alternatives in the other PSUs would remove very few acres associated within the clearings relative to total acres available within the PSUs. In addition, under the agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R), snags would be left within the disturbance acres where they do not pose a safety hazard and would newly designate old growth acres that would maintain the old growth characteristics. The analysis area PSUs would continue to provide sufficient quality and quantity of snags and replacement snags for viable populations of cavity habitat dependent wildlife species well above minimum standard 40 percent on National Forest System lands. Impacts to riparian habitat are negligible compared to the amount available with the PSUs and the 60 percent level would be maintained throughout the PSUs. Where clearings would occur on private and State lands under the transmission line alternatives, the proposed clearings are expected to have negligible effects compared to the existing snag level conditions.

Maintenance of down wood habitat is beneficial to both forest health and various wildlife species that are dependent on down woody material to fulfill life requirements. Based on the predominant habitat types and district surveys within old growth and past harvest units, the analysis area PSUs currently have high levels of down woody debris. Removal associated with the disturbance areas is expected to remove very little compared to what would remain available within the surrounding forested habitats under all alternatives. In addition, the retention of recommended levels of down wood materials would occur through retention of existing logs and felled snags under the agencies' transmission line alternatives, which would occur on both National Forest System and private and State lands. Proposed activities and implementation of design features would maintain the availability and distribution of down wood materials within the impacted PSUs at levels beneficial to wildlife.

State Requirements

Alternatives 3 and 4 would comply with the MMRA regarding disturbed lands being reclaimed to a post-mining land use with stability and utility comparable to that of the pre-mining landscape. Draft findings regarding compliance with MFSA requirements are discussed in the Summary, beginning on p. S-53.

3.25.3 Management Indicator Species

The KNF identified MIS species in the 1987 KFP because they were believed to act as barometers of change for a particular habitat. The species identified fall into different categories that include: 1) the species was identified by the USFWS as a threatened or endangered species and present on the KNF; 2) it is a species that is commonly hunted, fished, or trapped; or 4) they are a species believed to have special habitat needs that could be affected by management activities. As specified in the KFP, the KNF uses MIS, which act as representatives for an array of other species that use the same habitat, or with similar breeding and foraging habitat requirements, providing a tool for more accurately monitoring more than 300 different species of wildlife (USDA Forest Service 2003b) that occupy the KNF. Management Indicator Species (MIS) were chosen based on the following criteria: (1) the species can be easily monitored and (2) the species is susceptible to changes resulting from management activities. It is assumed that effects on MIS can be correlated to effects on other species with similar habitat requirements.

3.25.3.1 Regulatory Framework

3.25.3.1.1 Federal Requirements

The Organic Administration Act authorizes the Forest Service to regulate the occupancy and use of National Forest System lands. The Forest Service’s locatable minerals regulations are promulgated at 36 CFR 228, Subpart A. The regulations apply to operations conducted under the U.S. mining laws as they affect surface resources on National Forest System lands under the jurisdiction of the Secretary of Agriculture. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources. 36 CFR 228.8 also requires that mining operators take all practicable measures to maintain and protect fisheries and wildlife habitat which may be affected by the operations; and construct and maintain all roads so as to assure adequate drainage and to minimize or, where practicable, eliminate damage to soil, water, and other resource values.

The National Forest Management Act requires the Secretary of Agriculture to promulgate regulations specifying guidelines for land management plans that “provide for the diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet overall multiple-use objectives…” The “specific land area” (scale) for providing diversity is established in the framework as the area covered by the Forest Plan, or the entire KNF. One of the KFP goals is to “maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species… and in sufficient quality and quantity to maintain habitat diversity representative of existing conditions” (II-1 #7). In addition, the KFP includes a wildlife standard relevant to MIS that states that “the maintenance of viable populations of existing native and desirable non-native vertebrate species, as monitored through indicator species, will be attained through the maintenance of a diversity of plan communities and habitats” (II-22). The MIS designated for the KNF and the habitat they are intended to represent are identified in the KFP (KFP Vol. 2, Appendix 12), and shown in Table 196.

Table 196. KNF Management Indicator Species.

Species	Habitat Represented	Comments
Grizzly Bear (*Ursus arctos*)	General Forest	See section 3.25.5, *Threatened, Endangered, and Proposed Species*
Gray Wolf (*Canis lupus*)	General Forest	See section 3.25.4, *Sensitive Species*
Bald Eagle (*Haliaeetus leucocephalus)*	Rivers and Lakes	See section 3.25.4, *Sensitive Species*
Peregrine Falcon (*Falco peregrinus*)	Cliffs	See section 3.25.4, *Sensitive Species*
Elk (*Cervus elaphus*)	General Forest	
White-tailed Deer (*Odocoileus virginianus*)	General Forest	
Mountain Goat (*Oreamnos americanus*)	Alpine	
Pileated Woodpecker (*Dryocopus pileatus*)	Snag Habitat, Old Growth	See section 3.25.2, *Key Habitats*

The MIS described in this section are elk, white-tailed deer, mountain goat, and pileated woodpecker. Impacts on the grizzly bear are addressed in section 3.25.5*, Threatened, Endangered, and Proposed Species* and impacts on the bald eagle, gray wolf, and peregrine falcon are described in section 3.25.4, *Sensitive Species.*

3.25.3.1.2 State Requirements

The MFSA directs the DEQ to approve a transmission line if, in conjunction with other findings, the DEQ finds and determines that the facility would minimize adverse environmental impact, considering the state of available technology and the nature and economics of the various alternatives. An assessment of effects on big game species is part of the transmission line certification process. FWP is required to report DEQ information relating to the impact of the proposed site on FWP's area of expertise. The report may include opinions as to the advisability of granting, denying, or modifying the certificate.

3.25.3.2 Elk

Elk and white-tailed deer are two MIS that were selected to indicate change in general forest habitat. Summerfield (1991) recommends selecting one big game species as the focus of analysis in a particular area, because species winter requirements differ. The KNF and the FWP have developed management emphasis designations for elk by PSU (Johnson 2004a). In PSUs where elk is designated as high emphasis, elk will be the indicator for general forest habitat. For PSUs where elk is designated as low emphasis, whitetail deer will be the indicator for general forest habitat. For PSUs where elk is designated as moderate emphasis, the project biologist will designate the general forest indicator, based on site-specific information about elk and deer use in the PSU. Management emphasis ratings for elk are high in PSUs where maintaining elk security is a high priority, medium where elk are one of the primary resource considerations, and low where elk management is not a priority. The PSUs potentially affected by the Montanore Project are the Crazy and Silverfish PSUs. The Crazy PSU is assigned a medium elk emphasis rating, while the Silverfish PSU is assigned a high elk emphasis rating. Based on these management emphasis ratings, KFP direction, the biological potential of the area, state wildlife management objectives, public comments during scoping, information contained within the KNF Conservation Plan (Johnson 2004a), and site-specific knowledge of deer and elk use in the Crazy and Silverfish PSUs, the elk was selected as the general forest indicator for the Silverfish PSU and the white-tailed deer was selected as the general forest indicator for the Crazy PSU.

3.25.3.2.1 Analysis Area and Methods

Elk population ecology, biology, habitat description, and relationships identified by research are described in Thomas (1979), Lyon *et al*. (1985), Hillis *et al*. (1991), and Toweill and Thomas (2002). This literature helped inform the analysis of effects to elk and its habitat based on direction provided in the KFP (as amended) and is incorporated by reference. Elk population and harvest data come primarily from FWP. Additional information is provided by recent District wildlife observation records and KNF historical data (NRIS Wildlife).

The analysis area for evaluating direct, indirect and cumulative effects on individuals and their habitat on National Forest System lands is the Silverfish PSU, because activities in these areas could result in disturbance and displacement effects to elk (Figure 89). Elk emphasis areas were defined by the PSU, although adjacent planning areas were also considered for effects. Elk have home ranges that include both winter and summer use areas, which could extend beyond the Silverfish PSU. The PSU is large enough to account for effects on these various components of elk habitat and use in this area. Connectivity and movement within home ranges could be impacted by the proposed activities as well as activities in adjacent PSUs. To evaluate potential direct, indirect and cumulative impacts of the transmission line on elk on private and State land, the analysis area includes all land within a corridor 1 mile on each side of the alternative transmission line alignments. The boundaries for determination of population trend and contribution toward population viability are the FWP hunting districts (HD) 103 and 104 and the KNF, respectively. The analysis for elk was limited to the transmission line alternatives because the mine alternatives would not affect the Silverfish PSU.

Data sources used in this analysis include FWP hunting and population data, research, and plans; District vegetation layers; INFRA roads layers; TSMRS data; Summerfield (1991); and field surveys by District biologists and data collection crews. Potential effects to elk in the KNF are evaluated according to five effects indicators: cover/forage ratio, forage openings, habitat effectiveness (HE), security, and key habitat features. These indicators are described below. Potential effects to forage quality are also evaluated.

Cover/Forage Ratios

An important consideration when evaluating big game habitat is the distribution of cover and forage within a given area. Cover can be described as vegetation that provides protection from weather, predators, and humans. Two types of cover are considered for this analysis: hiding and thermal cover, based on Thomas (1979). Hiding cover is defined as vegetation capable of hiding 90 percent of an elk from human view at 200 feet. Thermal cover is defined as stands of conifers at least 40 feet tall with 70 percent crown closure. Forage areas are natural or man-made areas that do not qualify as either hiding or thermal cover. Re-examination of elk use of thermal cover and foraging areas indicates that providing thermal cover does not compensate for inadequate forage conditions (Cook *et al.* 1998). The ratio of cover to forage represents the percentage of the PSU that meets elk requirements for both cover and forage.

Effects of the alternatives on cover and forage are evaluated based on cover/forage ratios for summer and winter range, percent cover for combined MAs 15, 16, 17, and percent thermal cover on winter range in the Silverfish PSU. MA designations, goals, and standards are described in detail in section 3.15, *Land Use*. The KFP recommends a cover/forage ratio of 30/70 percent for elk winter range (for MA 10 and 11 combined). MAs 10 and 11 were delineated for the KFP and do not entirely overlap with elk winter range mapped by FWP (Figure 89). To avoid confusion with FWP winter range, for impacts evaluated on National Forest System land, winter range is referred to as MAs 10 and 11. Summerfield (1991) recommends 60 percent cover on winter range and summer range combined (for all MAs). On elk winter range, the cover should be at least 40 percent thermal cover. Summer range cover may include any combination of hiding and thermal cover (Ibid.). The KFP guideline for hiding and thermal cover on MAs 15, 16, and 17 for elk is greater than 15 percent. MAs 15, 16, and 17 are managed for timber production and do not necessarily correspond to areas of seasonal elk use.

Forage Openings

In general, use of foraging areas decreases when big game is required to venture more than 600 feet from cover (Thomas 1979). According to KFP guidelines, maximum opening size on National Forest System lands should generally be less than 40 acres. Forage openings are identified through TSMRS database queries to determine type and age of past harvest. For this analysis, effects of forest openings on elk are evaluated based on the regeneration harvest greater than 40 acres occurring after 1986. This analysis was based on a worst-case scenario for transmission line clearing effects and assumes that the entire transmission line clearing area would be cleared.

Habitat Effectiveness

The habitat effectiveness (HE) of an area refers to the percentage of habitat without open roads that is usable by elk outside of the hunting season. Numerous studies have shown a strong negative correlation between elk use of an area and the density of open roads even if those roads are only lightly traveled (Frederick 1991).

Lyon (1983) describes the underutilization of habitat along open roads by elk and developed a road density model that showed that an increase in open road density (ORD) results in a non-linear decrease in HE. The road density model from Lyon (1983) was used to derive the approximate HE level for the PSU and MAs within the PSU.

The KFP includes ORD standards for four MAs. ORD is measured as miles of open roads per square mile (mi/mi^2). The KFP standard for ORD in MA 12 (managed for big game summer range and timber production) is no more than 0.75 mi/mi^2, which equates to 68 percent HE (Lyon 1984). Meeting the ORD standard means that lands within this MA are providing important habitat for elk. On MAs 15, 16, 17, and 18, the KFP ORD standard is no more than 3.0 mi/mi^2, which equates to 38 percent HE. The KFP does not provide ORD standards for winter range (MAs 10 and 11); road use and timber harvest activities would normally be restricted during the winter in these MAs (December 1 to April 30).

All lands within the Silverfish PSU could provide elk habitat, including other MAs such as MA 2 (semi-primitive non-motorized recreation), MA 13 (old growth), and MA 14 (grizzly bear habitat). Determining HE levels only for those MA's with an ORD standard does not always reflect the amount of land useable by elk within the analysis area; therefore ORD, and the corresponding HE, were calculated for all National Forest system lands in the Silverfish PSU.

Christensen *et al*. (1993) defined levels of HE for elk management depending on the desired condition for elk in the management area. Where elk are a primary consideration for management, HE should be ≥ 50 percent (corresponding ORD of >1.85 mi/mi^2), while areas with HE levels ≥ 70 percent (corresponding ORD of 0.65 mi/mi^2) is expected to retain high elk use.

Effects of the alternatives on HE were evaluated based on ORD for National Forest System lands in MA 12, for the combined MAs 15, 16, 17 and percent HE on National Forest System lands in the Silverfish PSU. In all transmission line alternatives, the KNF would designate lands within a 500-foot corridor of the selected 230-kV transmission line on National Forest System lands as MA 23. This MA change would apply only to National Forest System lands currently not MA 23 but included in the right of way by any transmission line alternative, and would not apply to private lands crossed by the transmission line alternatives. ORD in MA 12 was calculated assuming all MA 12 within a 500-foot corridor of all transmission line alternatives would be changed to MA 23.

Security Habitat

Security areas are defined as areas that are larger than 250 contiguous acres in size and more than 0.5 mile from an open road (Hillis *et al*. 1991). Security habitat offers elk refuge and reduces their vulnerability during the hunting season. The size and availability of secure habitat can influence the age structure and composition of a herd (Leptich and Zager 1991; Unsworth and Kuck 1991; Lyon *et al*. 1997; Servheen *et al*. 1997; Jellison 1998; Canfield *et al*. 1999; FWP 2004a).

The KFP has no standard for security areas. A panel of state and federal wildlife biologists convened in 1996 to produce the document entitled "Integrating Kootenai National Forest Plan and Fish, Wildlife & Parks Elk Management Plan Final Task Force Report" (KNF and FWP 1997) which identifies security as an important component of elk habitat and indicated that it should be quantified based on methods used by Hillis *et al.* (1991). Hillis *et al*. (1991) recommends maintaining at least 30 percent of an elk's fall use area as security habitat. Because elk fall use areas could be anywhere within a PSU, the 30 percent minimum elk security standard is applied to all lands within a PSU. Security levels are defined in Appendix H-B of Johnson (2004a). Effects of the alternatives on elk security were evaluated based on the percent security in the Silverfish PSU.

Key Habitat Features

Moist environments are important to elk, providing high-quality forage, allowing regulation of body temperature, and providing wallowing areas used primarily by bull elk during the breeding season (Lyon *et al.* 1985; Toweill and Thomas 2002). Effects of the alternatives on key habitat features are evaluated based on the acres of wetlands potentially impacted. KFP standards for MAs 11 and 12 include avoidance of wallows, wet meadows and bogs when constructing roads. INFS standards for RHCAs, discussed in detail in section 3.6, *Aquatic Life and Fisheries*, provide additional protection of wallows, wet meadows, and bogs that occur in riparian areas.

Movement Areas

According to KFP direction, activities such as timber harvest should not interfere with wildlife movement patterns, and forested cover should be provided in harvest and thinning areas as movement corridors for wildlife in summer and winter range. In the KNF, movement corridors along ridgetops are especially important for elk. The analysis of impacts on movement corridors was based on District GIS mapping of topographical contours and is available in the Project record.

Alternative Mitigation Measures

The agencies' alternatives would include additional yearlong access changes through the installation of barriers or gates in several roads to mitigate for the loss of big game security and impacts (Figure 35). These road access changes are taken into account in elk HE, elk security, and road density calculations.

Additional road access changes may also occur on land acquired as part of the grizzly bear mitigation proposed by MMC or the agencies (see mitigation plan descriptions in sections 2.4, *Alternative 2- MMC's Proposed Mine*, and section 2.5, *Alternative 3—Agency Mitigated Poorman Impoundment Alternative*). Elk HE, elk security, and road density calculations do not take into account the effect of land acquisition requirement for grizzly bear mitigation.

Other mitigation measures incorporated into MMC's or the agencies' alternatives that could benefit elk include winter construction timing restrictions in elk winter range, prohibiting employees from carrying firearms, and monitoring road-killed animals along mine access roads to determine if improved access resulted in increased wildlife mortality. Impacts on elk on private and State land from the transmission line corridor were evaluated based on FWP winter habitat mapping (Figure 89); elk security generated from KNF roads data; FWP hunting and population data, research, and plans; KNF and FWP information on wildlife linkage and approach areas; and mapping of broad vegetation types shown on Figure 85.

3.25.3.2.2 Affected Environment

The Silverfish PSU is located in elk HD 104, which is one of six hunting districts in the Lower Clark Fork Elk Management Unit (EMU), described in the Statewide Elk Management Plan (FWP 2004a). The FWP evaluates elk population composition and trends based on total elk, calf/cow ratios, and bull/cow ratios observed during sampling surveys of a portion of the HD referred to as trend areas, harvest data, and hunter effort data (Brown, pers. comm. 2008). The area near the proposed mine facilities is not surveyed during trend surveys, and the most recent trend area survey for HD 104 was conducted in 2008 (FWP 2013a). No surveys were conducted for HD 104 between 2004 and 2007 (FWP 2013a). The average number of elk observed in the trend area for HD 104 from 1999 to 2008 was 182 elk, including an average of 17 bulls (FWP 2013a). Trend area survey goals established by the Statewide Elk Management Plan for HD 104 are between 180 and 270 elk (FWP 2004b). Heavy snowfall during the winter of 1996 to 1997 in northwest Montana resulted in higher than average winter mortality and poor calf production the following spring.

The elk population in northwest Montana has increased since the winter of 1996 to 1997 and remains stable (FWP 2004a; USDA Forest Service 2008c; FWP 2013b). Overall, the elk population in HD 104 has stabilized. Although high snowfall during the winter of 2007 to 2008 resulted in relatively high elk mortality and low calf production, impacts were significantly less than from the winter of 1996 to 1997 (Brown, pers. comm. 2008). During 2013, elk numbers in the lower Clark Fork EMU were stable with good calf and bull numbers seen during spring surveys (FWP 2013b).

The eastern segments of the transmission line alternatives would occur in HD 103, which is in the Salish EMU. An annual average of 164 elk, including 13 bulls, was observed during trend area surveys in HD 103 from 1977 to 2003 (FWP 2007a). Trend area survey goals for HD 103 are 260 elk (FWP 2007a). Some of the larger concentrations of elk in HD 103 occur in the Fisher and Thompson River valleys.

The KNF's 2007 Monitoring and Evaluation Report (USDA Forest Service 2008c), concluded that the elk population on the KNF appears to be increasing in the last few years based on FWP data. Observations made during FWP surveys counted a minimum of 1,951 elk in 2007, an increase of at least 173 individuals since the last reporting period in 2002. Since 1998, hunting season regulations changed allowing harvest of branch antlered bulls and cows by permit. This increase in population has reduced the average number of days needed to harvest an elk and has allowed FWP to increase the number of permitted cow/calf tags each season. Increased road restrictions and decommissioning in the last 20 years has improved elk security on the KNF, likely contributing to the population increase and steady numbers of large bulls observed since 2002.

Cover/Forage

As of the end of 2007, elk summer range in the Silverfish PSU is comprised of 99 percent cover and 1 percent forage habitat, while MAs 10 and 11 are comprised of 97 percent cover and 3 percent forage habitat. Cover to forage ratios in the Silverfish PSU indicate that the proportion of forage habitat is well below recommended levels. As noted in the Statewide Elk Management Plan (FWP 2004b), the quality of winter elk forage productivity is declining in the Lower Clark Fork EMU due to conifer encroachment, noxious weed infestations, and aging shrubs. The proportion of thermal cover in winter range (MAs 10 and 11) is 21 percent, which is below the 40 percent minimum recommended by Summerfield (1991). Research conducted by Cook *et al.* (1998) suggests that thermal cover may not enhance elk condition. MAs 15, 16, and 17 in the Silverfish PSU consist of 86 percent thermal and hiding cover combined, which is greater than the KFP recommended 15 percent minimum.

Most past harvest areas have recovered to the point they are no longer considered openings and contribute to the high cover to forage ratio in the PSU; there are 15 existing openings greater than 40 acres within proposed activity areas. Covered movement areas are found throughout the Silverfish PSU. Historically, wildfire would create a mosaic of successional stages and result in vegetative diversity in this area. In contrast, fire suppression and past timber management has resulted in a trend toward homogenous stand composition and structure consisting of high density stands of shade-tolerant species (see section 3.22, *Vegetation*) that reduce the presence and productivity of understory forage species. In summary, the PSU is currently outside the desired conditions for elk and other big game species with high cover and limited forage availability.

Habitat Effectiveness, Security Habitat, and Open Road Density

The existing MA 12 ORD of 1.29 mi/mi^2 equates to a HE of 57 percent, which does not meet the KNF ORD standard and has less effective habitat. The current ORD of 0.9 mi/mi^2 in MAs 15, 16, 17, and 18 with a corresponding HE of 66 percent meets (is less than the maximum allowed) KFP ORD standard and consequently has more effective habitat.

The high elk emphases rating for the Silverfish PSU is reflected by existing elk security habitat (57 percent) and HE (72 percent) that are greater than minimum levels recommended by Hillis *et al*. (1991) and Christensen *et al*. (1993).

Forage Openings

The Silverfish PSU contains 15 openings greater than 40 acres. The distance to cover may discourage elk from foraging in portions of these openings.

Key Habitat Features

Wetland that may provide potential wallowing areas for elk are described in section 3.23, *Wetlands and Other Waters of the U.S.*

Movement Areas

Movement corridors along ridgetops are especially important for elk, and most of these areas or travel ways are intact and providing hiding cover. Following a process developed by Servheen *et al.* (2003) and the Interagency Grizzly Bear Committee (IGBC) (2004), the KNF identified a wildlife approach area in the Fisher River valley between the Barren Peak and Teeters Peak areas to the west of US 2, and the Kenelty Mountain and Fritz Mountain areas to the east of US 2 (Brundin and Johnson 2008). An approach area is a zone of habitat where wildlife can safely and securely cross and move away from highways, railways, rivers, or other features that fragment habitat, impede movements, and elevate mortality risk. US 2 in the Fisher River valley between Raven and Brulee creeks (Figure 89) is a crossing area for many species of wildlife, including elk, white-tailed deer, grizzly bear, and moose migrating between summer ranges in the Cabinet Mountains and winter ranges in the Salish Mountains (Brown, pers. comm. 2008).

Impacts on Elk on State or Private Lands

Elk winter range is shown on Figure 89. The Montanore Project potentially affects elk winter range in the Fisher River and West Fisher Creek corridors and the southern exposures of Miller Creek. The majority of state and private land is heavily roaded and does not provide security habitat for elk (Figure 89).

Private land occupies the areas adjacent to US 2 in the wildlife approach area described above, most of which is heavily roaded and has been logged in the past 20 to 30 years. Regeneration has occurred on some of the logged stands, providing potential hiding cover.

3.25.3.2.3 Environmental Consequences

Impacts on elk habitat and percent elk security, habitat effectiveness, and open road densities in the Silverfish PSU and private and State lands in the analysis area from the various project features of the transmission line alternatives are shown in Table 197 and Table 198, and described in the following subsections. Elk is the MIS for the Silverfish PSU. Impacts associated with the mine alternatives would be limited to the Crazy PSU, where the white-tailed deer is the MIS for general forest species. Impacts on white-tailed deer in the Crazy PSU are described in the *White-tailed Deer* subsection.

Alternative A – No Transmission Line

No direct effects from alternative A would occur. Alternative A would not impact elk habitat and would maintain the existing vegetation condition on the landscape, including cover forage ratios, security habitat, and HE within the Silverfish PSU. Over time, with continued fire suppression and lack of active forest management, indirect effects of this alternative would include a continued trend toward later successional habitats. Forage habitat would decrease over time unless harvest or other stochastic events, such as a wildfire or windstorm, created additional forage. If these events resulted in large openings being created, new forage habitat may not be available to elk due to lack of cover within 600 feet. Until hiding cover develops (about 15 to 20 years, depending on site conditions), individual animals may be more vulnerable to predation and hunting mortality in areas where large openings develop following wildfire.

Table 197. Impacts on Elk Habitat by Transmission Line Alternative.

[1] Const = during transmission line construction.
[2] Ops = during transmission line operations.
[3] Security habitat is calculated by buffering all roads open during the fall (October 15 to November 30) by 0.5 mile. The remaining total area, which may consist of one or more habitat blocks greater than 250 acres, equals security habitat. Security habitat may include State and private lands, but no elk security habitat occurs on private or State land in the analysis area.
[4] Habitat Effectiveness is based on the relationship between open road density and habitat effectiveness, as described in Appendix H of Johnson (2004a).
[5] All MA 12 within a 500-foot corridor of the transmission line centerline would be reallocated to MA 23. Alternative A reflects the existing MA and ORD prior to reallocation. MA reallocation was taken into account in the action alternative road density calculations.
ORD = open road density.
Source: GIS analysis by ERO Resources Corp. using KNF data.

Introduced species that are often unpalatable to elk would continue to spread in the analysis area, displacing native forage species. Current Forest Service, state, and county-wide noxious weed management practices would continue to reduce noxious weed infestations. Overall, elk populations are expected to be maintained at a level commensurate with the available suitable habitat.

Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

Cover/Forage

In Alternative B, cover relative to forage habitat on Forest System land would decrease by 1 percent to 96 percent in MAs 10 and 11 and percent thermal cover relative to forage in MAs 10 and 11 would decrease by 1 percent to 20 percent in the Silverfish PSU (Table 197). Percent cover relative to forage habitat in summer range and percent cover in MAs 15, 16, and 17 in the Silverfish PSU would not change as a result of Alternative B. Alternative B would include the reallocation of MAs 10 and 11 in a 500-foot corridor along the transmission line to MA 23, which does not have a cover/forage standard. All disturbed areas, such as access roads, pulling and tensioning sites, and transmission line clearing areas, would be seeded with grass and shrub species after transmission line construction. Areas where trees were trimmed, but otherwise not disturbed, would be allowed to establish naturally as grassland or shrubland. Once vegetation is re-established, disturbed areas of winter range would provide additional forage habitat as forage species become established, thereby moving elk habitat conditions in the Silverfish PSU toward KFP objectives. Roads built for the installation of the transmission line would be redisturbed during line decommissioning. After the transmission line was removed, all newly constructed roads would be bladed, contoured, and seeded. Once vegetation re-established, redisturbed areas would provide forage habitat. Alternative B would increase the spread and establishment of noxious weeds and other introduced species associated with surface disturbance. Alternative B would have the largest area of surface disturbance associated with new or upgraded road construction and timber clearing of all transmission line alternatives, but would have the least area of vegetation clearing. Surface disturbances and continued road use would increase the risk of spread of noxious weed and other introduced species that are unpalatable to elk. New roads would be reseeded as an interim measure, but used for maintenance activities, as necessary. MMC's weed control and other BMPs would be implemented. Current populations of elk would likely be maintained in Alternative B because changes to cover to forage ratios would be 1 percent or less, and because while cover would decrease relative to forage, the Silverfish PSU provides an abundance of cover.

Open Road Density, Security Habitat, and Habitat Effectiveness

Alternative B includes an access change in NFS road #4724 from April 1 to June 30 to mitigate for impacts on grizzly bears. The seasonal access change in NFS road #4724 is taken into account in ORD calculations but would not affect percent elk security habitat as motorized access could occur during the fall hunting season.

Within the Silverfish PSU MA 12 ORD at 1.29 mi/mi^2 currently does not meet the KFP standard (Table 198). Alternative B would include the reallocation of MA 12 in a 500-foot corridor along the transmission line to MA 23. During Alternative B line construction, MA 12 ORD in the Silverfish PSU would increase to 1.35 mi/mi^2 due to new or opened roads located on MA 12 lands outside the 500 –foot transmission line corridor and would require a site-specific KFP amendment to exceed the MA 12 standard for ORD. Specifically, the site specific amendment for temporary increases in ORD would apply to MA 12 in the northwest quarter of section 16 T2N, R30W. During operations MA 12 ORD would lower to (1.30 mi/mi^2), slightly higher than existing conditions. The alternative also increases ORD to 1.0 mi/mi^2 in MAs 15, 16, 17, and 18, where the KFP standard would be met (Table

198). ORD would return to existing conditions in MAs 15, 16, 17, and 18 during transmission line operations.

During Alternative B line construction, ORD in the Silverfish PSU would increase to 1.35 mi/mi^2 in MA 12, where ORD is currently worse than the KFP standard and would require a site-specific KFP amendment to exceed the MA 12 standard for ORD. The alternative also increases ORD to 1.0 mi/mi^2 in MAs 15, 16, 17, and 18, where the KFP standard would be met (Table 198). Alternative B would include the reallocation of MA 12 in a 500-foot corridor along the transmission line to MA 23. Where new or opened roads associated with Alternative B would be outside the 500-foot transmission line corridor. Specifically, the site-specific amendment for temporary increases in ORD would apply to MA 12 in the northwest quarter of section 16 T2N, R30W.

Alternative B would decrease both percent elk security habitat and HE in the Silverfish PSU by 2 percent during construction; both measurement criteria would remain better than recommended guideline minimum levels. During construction, HE would decrease by one percent in MA 12, but would remain at existing levels in MAs 15, 16, 17, and 18. During transmission line operations, security habitat and HE would return to existing levels.

The transmission line corridor would cross a 2,108-acre block of elk security habitat in the Miller Creek drainage in the Silverfish PSU (Figure 89). The transmission line clearing area in the Miller Creek drainage would include 35 acres of elk security habitat. Some of this area would not be cleared because it would be in a valley that would be spanned by the transmission line, or is currently fairly open habitat due to past regeneration harvest. Clearing of about 0.5 mile (9 acres) of elk security habitat would provide improved access for forest users along the ridgeline between the Miller Creek and Midas Creek drainages, reducing the effectiveness of security habitat for elk during the big game hunting season for the duration of the project. After the transmission line was decommissioned, forest cover would return slowly to the clearing area and elk security habitat would return to pre-mine conditions.

Although the new road prism in Alternative B would remain during transmission line operations, roads opened or constructed for transmission line access would be gated or barriered on National Forest System lands after transmission line construction. Roads opened or constructed for transmission line access on private land would be gated after transmission line construction. During the final Closure Phase following mine closure, the transmission line would be removed, roads and other areas of surface disturbance reclaimed on National Forest System land, and trees along the line allowed to grow. The increase in ORD and the decrease in security habitat and habitat effectiveness could displace individual elk to less disturbed areas in the short term, until transmission line construction was complete. In Alternative B, no construction would occur during winter (assumed to be December 1 to April 30) on winter range, and no motorized activity would occur from April 1 to June 15 in bear habitat in the Miller Creek and Midas Creek drainages. The winter and spring construction timing restrictions would reduce displacement effects. Because percent security habitat and habitat effectiveness would remain above recommended levels during Construction and Operations Phases (Table 198), and because transmission line disturbance would be short-term, overall populations would not likely be affected.

Habitat effectiveness and percent security do not take into account the potential effects of disturbance from helicopter use during line stringing. Helicopter use could contribute to short-term displacement of individual elk from the transmission line corridor. Helicopter use for line stringing would occur during a relatively short period (about 10 days). Except for annual inspection and infrequent maintenance operations, helicopter use and other construction activities would cease after transmission line construction until decommissioning. Helicopter use and other activities could result in short-term disturbance of elk during line decommissioning. Overall elk populations would not likely be affected by helicopter activity because sufficient security habitat would be available for any elk displaced due to short-term disturbance, and because construction timing restrictions would reduce the extent of potential displacement effects.

Forage Openings

One opening in forest cover greater than 40 acres would be created by Alternative B. No point in the transmission line clearing area would be greater than 600 feet from cover.

Key Habitat Features

The clearing area for Alternative B would include about 4 acres of wetland habitat providing potential wallowing areas for elk. Direct effects to wetlands are expected to be mostly avoided by placement and location of transmission line facilities and roads outside of wetlands and streams. Less than 0.1 acre of wetlands and streams would be affected by new or upgraded road construction.

Movement Areas

Alternative B could interfere with elk movement in the Silverfish PSU where it followed the ridges between Midas Creek and Howard Creek, and Midas Creek and the unnamed tributary to Miller Creek. Elk could be discouraged from using these areas during transmission line construction due to increased noise from helicopters and machinery and the presence of humans, but these effects would be short-term. The width of clearing area would not likely be great enough to affect elk movement in this area after the Construction Phase because sufficient cover would be present.

The eastern segment of the Alternative B transmission line alignment would occur within the wildlife approach area in the Fisher River valley in the description of the affected environment above. The proximity of this alignment to US 2 would result in a widening of disturbed area and could potentially discourage elk movement within the approach area by decreasing cover. Transmission line construction activities could cause elk to change their traditional movement patterns within this approach area, but these effects would be short-term because human-caused disturbance directly related to the project would cease when the transmission line construction were completed. Once revegetated, cleared areas could provide additional forage habitat. Some shrub and tree cover would be maintained in the transmission line right-of-way because only the largest trees would be removed, and would continue to provide cover. Given that most of the approach area potentially affected by Alternative B is generally heavily roaded and has been logged in the past 20 to 30 years, and because of the short-term nature of human-caused disturbance, it is not likely that elk movement within the approach area would be greatly affected by Alternative B.

Impacts on Elk on State and Private Lands

Alternative B would not affect State lands. Alternative B would affect about 124 acres of elk winter range on all lands in the analysis area, including 97 acres on private lands, primarily in the Miller Creek drainage and along the Fisher River valley (Table 197 and Figure 89). Direct impacts on winter range would include a reduction in thermal and hiding cover and, once the transmission line corridor was revegetated, an increase in forage habitat. Short-term disturbance impacts in elk winter range from transmission line construction would be minimized by restricting construction in elk winter range. Alternative B would result in increases in road densities on private lands. Roads opened or constructed for transmission line access on private land would be gated after transmission line construction, but could result in a reduction of elk security habitat and increased elk mortality if hunting access were allowed. Short-term habitat displacement could occur in the analysis area during transmission line construction as a result of increased road use during construction and helicopter use during line stringing. Helicopter use could contribute to short-term displacement of individual elk from the transmission line corridor. Helicopter use for line stringing would occur during a relatively short period (about 10 days), Except for annual inspection and infrequent maintenance operations, helicopter use and other construction activities would cease after transmission line construction until decommissioning. Helicopter use and other activities could result in short-term disturbance of elk during line decommissioning. Because private lands generally have high road densities and have been logged in the past 20 to 30 years, and because of the short-term nature of human-caused disturbance, overall, elk populations on private land, including the Sedlak Park Substation and loop line, would not likely be affected by Alternative B.

Private land in the eastern segment of the Alternative B transmission line alignment would occur within the wildlife approach area in the Fisher River valley described above for the affected environment. Potential effects of Alternative B, including construction of the Sedlak Park Substation and loop line, on elk use of the wildlife approach area would be the same as described above for National Forest System lands.

The risk of replacement of native forage species with unpalatable species would be the same as described above for National Forest Systems lands, except that new roads on private land would not be reseeded, potentially increasing the spread of noxious weeds and reducing available forage.

Alternative C-R – Modified North Miller Creek Transmission Line Alternative

Cover/Forage

The effects of Alternative C-R on cover-to-forage ratios in the Silverfish PSU would be the same as Alternative B, except that Alternative C-R would not reduce the percent thermal cover in MAs 10 and 11, but would reduce percent cover in MAs 15, 16, and 17 by 2 percent in the Silverfish PSU. Current populations of elk would likely be maintained in Alternative C-R because changes to cover to forage ratios would be 2 percent or less, and because while cover would decrease relative to forage, the Silverfish PSU provides an abundance of cover.

The effects of Alternative C-R on the risk of replacement of native forage species with unpalatable introduced species would be less than those described for Alternative B. The agencies' noxious weed mitigation measures would be implemented in the agencies' transmission line alternatives. To the extent possible, MMC would survey all proposed ground disturbance areas for noxious weeds before initiating disturbance. Where noxious weeds were found, MMC would treat infestations the season before the activity was planned. For example, if timber clearing were planned to be in the spring or early summer, the survey and control would be implemented the previous fall. Areas surveyed would include all areas designated for timber removal. MMC would describe in final design plans the extent of which surveys and pretreatment would not be feasible. The proposed survey and treatment approach would be a part of the final Weed Control Plan, to be reviewed and approved by the lead agencies. Helicopter use for vegetation clearing in some areas would minimize the potential for exotic species introduction associated with road construction or improvement and the extent of vegetation clearing would be greater. The agencies' modifications to MMC's proposed weed control plan for Alternative B would more effectively control the spread of weeds, minimizing the replacement of forage species.

Open Road Density, Security Habitat, and Habitat Effectiveness

Alternative C-R would include access changes (installation of barriers or gates and public access restrictions) in several roads to mitigate for the loss of big game security and impacts on grizzly bear (Figure 35). These access changes are taken into account in security, HE, and ORD calculations.

Within the Silverfish PSU MA12 ORD at 1.29 mi/mi^2 currently does not meet the KFP standard (Table 198). Alternative C-R would include the reallocation of MA 12 in a 500-foot corridor along the transmission line to MA 23 prior to activity. During Alternative C-R line construction, MA 12 ORD in the Silverfish PSU would increase to 1.31 mi/mi^2 due to new or opened roads located outside the 500-foot transmission line corridor. During operations MA 12 ORD would lower to 1.30 mi/mi^2. Alternative C-R would require a site specific KFP amendment for exceeding ORD in MA 12 during construction and operations in the northwest quarter of section 16 T27N, R30W. During construction, Alternative C-R would increase ORD to 1.4 mi/mi^2 in MAs 15, 16, 17, and 18, where the KFP standard is met (Table 198). During operations, ORD would return to existing conditions in MAs 15, 16, 17, and 18.

Alternative C-R would decrease percent elk security habitat and HE in the Silverfish PSU by 3 percent, respectively, during construction; both measurement criteria would remain better than the KFP-recommended minimum levels and would return to existing conditions during operations.

The transmission line corridor in Alternative C-R would cross a 2,108-acre block of existing elk security habitat in the Miller Creek drainage and a 1,597-acre block of existing elk security habitat in the West Fisher Creek drainage (Figure 89).). Although the transmission line clearing area in these segments of Alternative C-R would include more elk security habitat than Alternative B (about 59 acres for Alternative C-R), the general effects on forest user access of the clearing area would be the same as Alternative B.

The status of new or opened roads associated with Alternative C-R would be the same as Alternative B, except that on National Forest System lands, the status of roads opened or constructed for transmission line access would be changed to intermittent stored service after line installation was completed. Like Alternative B, in Alternative C-R the road prism would remain and new roads would be gated or barriered on National Forest System land after transmission line construction. In Alternative C-R, new transmission line roads on National Forest System lands would be decommissioned and revegetated after closure of the mine and removal of transmission line. The increase in ORD and the decrease in security habitat could displace individual elk to less disturbed areas in the short term, until transmission line construction was complete. In Alternative C-R, all construction and decommissioning activities on National Forest System and State lands would occur between June 16 and October 14, eliminating construction disturbance during winter and spring. Because percent security habitat and HE would remain above recommended levels during Construction and Operations Phases (Table 198), and because transmission line disturbance would be short-term, overall populations would not likely be affected.

HE and percent security do not take into account the potential effects of helicopter use during construction. Helicopter use could contribute to short-term displacement of individual elk from the transmission line corridor. In Alternatives C-R, D-R, and E-R, two seasons of helicopter construction would occur and the total duration of helicopter use each season would be about 2 months because helicopters would be used for vegetation clearing and structure construction. The type and duration of impacts from helicopter use for line stringing would be the same as Alternative B (about 10 days). Except for annual inspection and infrequent maintenance operations, helicopter use and other construction activities would cease after transmission line construction until decommissioning. Helicopters use and other activities could result in short-term disturbance of elk during line decommissioning. Overall elk populations would not likely be affected by helicopter activity because sufficient security habitat would be available for any elk displaced due to short-term disturbance.

Forage Openings

New forage openings would be the same for Alternative C-R as Alternative B.

Key Habitat Features

The clearing area for Alternative C-R would include about 2 acres of wetland habitat providing potential wallowing areas for elk. Direct effects to wetlands are expected to be mostly avoided by placement and location of transmission line facilities and roads outside of wetlands and streams.

Movement Areas

Alternative C-R may interfere with elk movement where it would follow the ridges between Midas Creek and Howard Creek, Midas Creek and the unnamed tributary to Miller Creek, and Miller Creek and West Fisher Creek and the east-facing ridge north of the Sedlak Park Substation. Elk could be discouraged from using these areas during transmission line construction due to increased noise from helicopters and machinery and the presence of humans, but these effects would be short-term. The width of clearing area would not likely be great enough to affect elk movement in this area after the Construction Phase because sufficient cover would be present.

A relatively small segment of the Alternative C-R transmission line would cross the Fisher River valley in the wildlife approach area, potentially discouraging elk movement in a localized area due to transmission line construction activities. These effects would be short-term because human-caused disturbance directly related to Alternative C-R would cease when the transmission line construction was completed. Given that the area of the approach area potentially affected by Alternative C-R is generally heavily roaded and has been logged in the past 20 to 30 years, and because of the short-term nature of human-caused disturbance, it is not likely that this alternative would greatly affect elk movement within the approach area.

Impacts on Elk on State and Private Lands

Alternative C-R would affect about 161 acres of elk winter range on all lands in the analysis area, including 108 acres on state and private lands, primarily in the Miller Creek, West Fisher Creek, and Fisher River drainages (Table 197 and Table 198). Direct impacts on winter range would include a reduction in thermal and hiding cover and, once the transmission line corridor was revegetated, an increase in forage habitat. Short-term disturbance impacts in elk winter range from transmission line construction would be minimized by restricting construction during the winter. Alternative C-R would result in increases in road densities on state and private lands. Roads opened or constructed for transmission line access on private land would be gated after transmission line construction, and could result in a reduction of elk security habitat and increased elk mortality if hunting access were allowed. Short-term habitat displacement could occur in the analysis area during transmission line construction as a result of increased road use and helicopter use during line stringing. Short-term impacts on private land from road and helicopter use would be the similar to Alternative B, but less extensive for Alternative C-R. Within the Silverfish PSU, short-term impacts on State trust lands from road and helicopter use would be similar to impacts on National Forest System lands. This is because mitigations applied to State trust land would be consistent with mitigations applied to affected National Forest System lands. Private land in the analysis area currently has high road densities and overall elk populations would not likely be affected. Because State and private lands generally have high road densities and have been logged in the past 20 to 30 years, and because of the short-term nature of human-caused disturbance, overall, elk populations on private and State land, including the Sedlak Park Substation and loop line, would not likely be affected by Alternative C-R.

Private and State land in the eastern segment of the Alternative C-R transmission line alignment would occur within the wildlife approach area. The segment of Alternative C-R that would parallel US 2 would be primarily on private land, would be located upslope and out of the Fisher River valley, and would not likely affect elk movement in the approach area. Other potential effects of Alternative C-R on elk use of the wildlife approach area would be the same as described above for National Forest System lands.

Alternative D-R – Miller Creek Transmission Line Alternative

Cover/Forage

Alternative D-R would have the same effect on the proportion of cover relative to forage habitat as Alternative C-R, except that Alternative D-R would reduce percent cover/forage in MAs 15, 16, and 17 in the Silverfish PSU by 4 percent.

The effects of Alternative D-R on the quality of forage due to the introduction of unpalatable species are similar to those described for Alternative C-R, except that the risk of replacing forage species with introduced species would be greater due to a longer clearing area.

Open Road Density, Security Habitat, and Habitat Effectiveness

Alternative D-R would include the same road access changes described for Alternative C-R, except that in Alternative D-R the entire length of NFS road #4725 would be closed before transmission line construction (Figure 35). Other than the differences in access to NFS road #4725, the status, use, and reclamation of new or opened roads associated with the transmission line would be the same for Alternative D-R as Alternative C-R.

The current ORD for MA 12 lands of 1.29 mi/mi^2 within Silverfish PSU exceeds the KFP standard (Table 198). Alternative D-R would include the reallocation of MA 12 in a 500-foot corridor along the transmission line to MA 23. During Alternative D-R line construction, ORD in MA 12 would increase to 1.30 mi/mi^2 due to new or opened roads located outside the 500-foot transmission line corridor. During operations, MA 12 ORD would return to the existing condition. During both construction and operations, Alternative D-R would require a site specific KFP amendment for MA 12 for temporary increases in ORD, and exceeding current KFP standards respectively. These MA changes would occur in the southeast quarter of section 19 T27N, R30W.

Within the Silverfish PSU, existing ORD for lands in MAs 15, 16, 17, and 18 is at 0.9 mi/ mi^2 and meets the KFP standard, (Table 198). ORD for these MAs would increase to 1.5 mi/ mi^2 during construction and would return to existing conditions during operations.

During construction, Alternative D-R would decrease percent elk security habitat and HE in the Silverfish PSU by 1 and 3 percent, respectively; both measurement criteria would remain better than the KFP-recommended minimum levels. Percent elk security and HE in the Silverfish PSU would return to existing conditions during operations.

Alternative D-R would include the reallocation of MA 12 in a 500-foot corridor along the transmission line to MA 23. Where new or opened roads associated with Alternative D-R would be outside the 500-foot transmission line corridor, a site specific KFP amendment would be required to allow for exceedance of the ORD standard in MA 12 during transmission line construction and operations. Specifically, the KFP amendment for temporary increases in ORD would apply to MA 12 in the southeast quarter of section 19 T27N, R30W.

Like Alternative C-R, the transmission line corridor in Alternative D-R would cross the edge of a 1,597-acre block of existing elk security habitat in the West Fisher Creek drainage (Figure 89). The transmission line clearing area in this segment of Alternative D-R would include about 11 acres of elk security habitat. The effects on forest user access of clearing would be the same as Alternative B. After the transmission line was decommissioned, forest cover in the clearing area would slowly return to pre-mine conditions.

The increase in ORD and the decrease in security habitat could displace individual elk to less disturbed areas in the short term, until transmission line construction was complete. In Alternative D-R, short-term elk displacement due to helicopter construction and stringing the transmission line would be similar to Alternative C-R, except that the extent of helicopter use would be less. In Alternative D-R, all construction and decommissioning activities on National Forest System and State lands would occur between June 16 and October 14, eliminating construction disturbance during winter and spring. Because percent security habitat and HE would remain above recommended levels during operations (Table 198), and because transmission line disturbance would be short-term, overall populations would not likely be affected.

Forage Openings

New forage openings would be the same for Alternative D-R as Alternative B.

Key Habitat Features

The effect on key habitat features would be the same for Alternative D-R as Alternative C-R.

Movement Areas

Like Alternative C-R, Alternative D-R could interfere with elk movement where it followed the east-facing ridge north of the Sedlak Park Substation and crosses the ridges between Miller Creek and West Fisher Creek, and Miller Creek and Howard Creek. Elk could be discouraged from using these areas during transmission line construction due to increased noise from helicopters and machinery and the presence of humans, but these effects would be short-term. The width of clearing area would not likely be great enough to affect elk movement in this area after the Construction Phase because sufficient cover would be present.

Potential effects of Alternative D-R on elk movement in the wildlife approach area would be the same as Alternative C-R.

Impacts on Elk on State and Private Lands

Impacts of Alternative D-R on elk would be the same as Alternative C-R (Table 197 and Figure 89).

Alternative E-R – West Fisher Creek Transmission Line Alternative

Cover/Forage

The effects of Alternative E-R on cover-to-forage ratios in the Silverfish PSU would be the same as Alternatives C-R and D-R except that Alternative E-R would decrease cover relative to forage habitat in MAs 10 and 11 by 2 percent to 95 percent in the Silverfish PSU and would not change the cover-to-forage ratio in MAs 15, 16, and 17. The effects of Alternative E-R on the quality of forage due to the introduction of unpalatable species are similar to those described for Alternatives C-R and D-R, except that the risk of replacing forage species with introduced species would be greater due to a longer clearing area.

Open Road Density, Security Habitat, and Habitat Effectiveness

Alternative E-R would include the same changes in road access for mitigation as described for Alternative D-R. The status, use, and reclamation of new or opened roads associated with the transmission line would be the same for Alternative E-R as Alternative D-R where the transmission line would follow the same alignment. Use and reclamation of new or opened roads in Alternative E-R would differ from Alternative D-R where the two alignments diverged.

Alternative E-R impacts on ORD would be the same as Alternatives C-R and D-R except that during construction, ORD in MA 12 in the Silverfish PSU would increase to 1.64 mi/mi^2 and ORD in MAs 15, 16, 17, and 18 would not change (Table 198). Alternative E-R impacts on percent security habitat and habitat effectiveness would be the same as Alternative D-R. Also, the site specific KFP amendment for exceeding the MA 12 ORD standard outside of the 500-foot transmission line corridor would apply to transmission line construction and operations in the eastern half of section 30, the western half of section 29, the northeastern quarter of section 31, the northwestern quarter of section 32, and the southeast quarter of section 19 T27N, R30W. Unlike Alternatives B, C-R, and D-R, Alternative E-R would not affect ORD in MAs 15, 16, 17, and 18. Short-term elk displacement due to helicopter construction and stringing the transmission line in areas other than elk security habitat would be similar to Alternatives C-R and D-R, except that the linear extent of helicopter activity would be greater.

The increase in ORD and the decrease in security habitat could displace individual elk to less disturbed areas in the short term, until transmission line construction was complete. In Alternative E-R, short-term elk displacement due to helicopter construction and stringing the transmission line would be similar to Alternatives C-R and D-R, except that the extent of helicopter use would be greater. In Alternative E-R, all construction and decommissioning activities on National Forest System and State trust lands would occur between June 16 and October 14, eliminating construction disturbance during winter and spring. Because percent security habitat and HE would remain above recommended levels during operations (Table 198), and because transmission line disturbance would be short-term, overall populations would not likely be affected.

Forage Openings

New forage openings would be the same for Alternative E-R as Alternative B.

Key Habitat Features

The effect on key habitat features would be the same for Alternative E-R as Alternative C-R.

Movement Areas

Alternative E-R could interfere with elk movement where it followed the east-facing ridge north of the Sedlak Park Substation and crossed the ridge between West Fisher and Howard creeks. Elk could be discouraged from using these areas during transmission line construction due to increased noise from helicopters and machinery and the presence of humans, but these effects would be short-term. The width of clearing area would not likely be great enough to affect elk movement in this area after the Construction Phase because sufficient cover would be present.

Potential effects of Alternative E-R on elk movement in the wildlife approach area would be the same as Alternatives C-R and D-R.

Impacts on Elk on State and Private Lands

Alternative E-R would affect the least amount of elk winter range (about 103 acres) on all lands in the analysis area. About 97 acres of elk winter range on state and private land would be affected by Alternative E-R, primarily in the Fisher River and West Fisher Creek drainages (Table 197 and Figure 89). Otherwise, impacts of Alternative E-R on elk on private and State lands would be the same as Alternatives C-R and D-R, except that in Alternative E-R the effects of helicopter use and the risk of replacing forage species with introduced species would be more extensive due to a longer clearing area.

Combined Mine-Transmission Line Effects

Impacts on elk habitat in the analysis area from combined mine-transmission line alternatives are described below and shown in Table 199.

Cover/Forage

The combined mine-transmission line alternatives would not change the percent cover to forage in summer range or the percent of thermal cover in MAs 10 and 11. All alternatives would result in a 1 to 2 percent decrease decreases in cover relative to forage habitat in MAs 10 and 11, with Alternatives 3E-R and 4E-R decreasing cover the most. All transmission line alternatives would include the reallocation of MAs 10 and 11 in a 500-foot corridor along the transmission line to MA 23, which does not have a cover/forage standard. Alternatives 2B, 3E-R, and 4E-R would not affect cover in MAs 15, 16, and 17, while Alternatives 3C-R, 3D-R, 4C-R, and 4D-R would reduce cover in MAs 15, 16, and 17 by 2 to 4 percent. Alternatives 3D-R and 4D-R would have the least impact on cover-to-forage ratios, but would reduce percent cover in MAs 15, 16, and 17 the most (by 4 percent). Cover to forage ratios in the Silverfish PSU indicate that the proportion of forage habitat is well below recommended levels. Current populations of elk would likely be maintained in all combined mine-transmission line alternatives because changes to cover to forage ratios would be 4 percent or less, and because while cover would decrease relative to forage, the Silverfish PSU provides an abundance of cover.

Open Road Density, Security Habitat, and Habitat Effectiveness

Alternative 2B includes an access change in NFS road #4724 from April 1 to June 30 to mitigate for impacts on grizzly bears and the agencies' alternatives would include access changes (installation of barriers or gates and public access restrictions) in numerous roads to mitigate for the loss of big game security and impacts on grizzly bear (Figure 35). These access changes are taken into account in security, habitat effectiveness, and ORD calculations.

Table 199. Impacts on Elk Habitat by Combined Mine-Transmission Line Alternative.

Elk Winter Range Impacted (acres)[6]	0	124	161	128	103	161	128	103

NA = Does not apply.
Impacts shown are for the transmission line Construction Phase, which represents maximum estimated impacts.
[1] Elk summer range includes all MAs except MAs 10 and 11.
[2] MAs 10 and 11 are managed for big game winter range; all MAs 10 and 11 within a 500-foot corridor of the transmission line centerline would be reallocated to MA 23.
[3] Transmission line corridor is counted as one opening. Other than the corridor length, no portion of the corridor would be greater than 600 feet to cover.
[4] Key habitat features such as bogs, wallows, and wet meadows are represented by wetlands, as described in section 3.23, *Wetlands and Other Waters of the U.S.* Values shown are wetlands and streams within clearing area of the transmission line alternatives from Table 186.
[5] Movement areas are represented by ridgelines of third order or larger drainages.
[6] Based on 2008 FWP mapping.
Source: GIS analysis by ERO Resources Corp. using KNF data and 2008 FWP mapping.

In all combined mine-transmission line, new road prisms would remain during transmission line operations. Roads opened or constructed for transmission line access would be gated or barriered on National Forest System land after transmission line construction. In the agencies' alternatives, roads on National Forest System lands would be placed into intermittent stored service after line installation was completed. Intermittent stored service roads would be closed to traffic and would be treated so they would cause little resource risk if maintenance were not performed during the operation period of the mine and before their future need. The service roads would not be used for routine maintenance of the transmission line, but could be used for emergency repairs, such as a damaged insulator. During the final Closure Phase following mine closure, the transmission line would be removed, roads reclaimed, and all disturbed areas revegetated. In the agencies' alternatives, roads on National Forest System lands would be decommissioned at mine closure and transmission line decommissioning. Roads opened or constructed for transmission line access on private land would be gated after transmission line construction. Management of newly constructed roads on Plum Creek land after the transmission line was removed would depend on the easement agreement between Plum Creek and MMC.

Habitat effectiveness and percent security do not take into account the potential effects of disturbance from helicopters. Disturbance from helicopter use and other transmission line construction activities are described for Alternatives B, C-R, D-R, and E-R above.

Alternatives 3C-R, 3D-R, 4C-R and 4D-R would increase ORD in MAs 15, 16, 17, and 18 from between 0.2 mi/mi^2 and 0.3 mi/mi^2 during transmission line construction (Table 200). Alternatives 2B and 3E-R and 4E-R would not affect ORD in MAs 15, 16, 17, and 18 during transmission line construction. None of the combined mine-transmission line alternatives would increase ORD in MAs 15, 16, 17, and 18 during operations, and they would decrease by 0.2 mi/mi^2 in Alternatives 3D-R and 4D-R.

During transmission line construction, increases in ORD in MA 12 would range from 0.01 mi/mi^2 for Alternatives 3D-R and 4D-R to 0.35 mi/mi^2 for Alternatives 3E-R and 4E-R. During transmission line operations, ORD in MA 12 would return to existing conditions in Alternatives 3D-R and 3E-R, but would increase by 0.01 mi/mi^2 in Alternatives 2B, 3C-R, 4C-R, 3E-R and 4E-R.

All combined mine-transmission line alternatives would include the reallocation of MA 12 in a 500-foot corridor along the transmission line to MA 23. Where new or opened roads associated with the combined mine-transmission line alternatives would be outside the 500-foot transmission line corridor, a site specific KFP amendment to allow for increased ORD in MA 12 would be necessary. Site specific KFP amendments for increases in ORD in MA 12 would be needed for Alternatives 2B, 3C-R and 4C-R, 3E-R, and 4E-R during transmission line construction and operations, and for Alternatives 3D-R and 4D-R during transmission line construction.

All combined mine-transmission line alternatives would result in 1 to 3 percent less elk security habitat in the Silverfish PSU during transmission line construction. Percent elk security habitat would return to existing levels following transmission line construction.

All combined mine-transmission line alternatives would result in 3 percent less habitat effectiveness in the Silverfish PSU during construction. Following transmission line construction, habitat effectiveness would return to existing levels.

Increases in ORD and the decrease in security habitat and habitat effectiveness could displace individual elk to less disturbed areas in the short term, until transmission line construction was complete. Overall populations would not likely be affected.

Table 200. Effects to Elk Habitat Components on National Forest System Land in the Silverfish PSU by Combined Mine and Transmission Line Alternative.

ORD in MAs 15, 16, 17, and 18 (mi/mi^2) Standard is,3.0	0.9	0.9	0.9	1.2	0.9	1.1	0.7	0.9	0.9	1.2	0.9	1.1	0.7	0.9	0.9

[1] Const = during mine construction.
[2] Ops = during transmission line operations.
[3] Security habitat is calculated by buffering all roads open during the fall (October 15 to November 30) by 0.5 mile. The remaining total area, which may consist of one or more habitat blocks greater than 250 acres, equals security habitat. Security habitat may include State and private lands, but no elk security habitat occurs on private or State land in the analysis area.
[4] Habitat Effectiveness is based on the relationship between open road density and habitat effectiveness, as described in Appendix H of Johnson (2004a).
[5] All MA 12 within a 500-foot corridor of the transmission line centerline would be reallocated to MA 23.
ORD = open road density.
Source: GIS analysis by ERO Resources Corp. using KNF data.

Overall, road densities, percent security habitat, and habitat effectiveness would likely improve through the grizzly bear land acquisition requirement. Acquired parcels would be managed for grizzly bear use in perpetuity, and could improve road densities, percent security habitat, and habitat effectiveness where roads could be closed. The agencies' land acquisition requirement would likely be more effective at reducing road densities than MMC's proposed land acquisition because more land would be protected.

Forage Openings

In all combined mine-transmission line alternatives, one opening greater than 40 acres would be created. No point in this opening created by the transmission line clearing area would be greater than 600 feet from cover.

Key Habitat Features

The agencies' alternatives would potentially affect 2 acres of wetland habitat providing potential wallowing areas for elk in the Silverfish PSU, while Alternative 2B would potentially impact 4 acres. Direct effects to wetlands are expected to be mostly avoided by placement and location of transmission line facilities and roads outside of wetlands and streams.

Movement Areas

The agencies' alternatives may interfere with elk movement where it followed the east-facing ridge north of the Sedlak Park Substation. Alternative 2B would be located at a lower elevation in the Fisher River valley and would not impact this area. Alternatives 2B, 3C-R, and 4C-R may interfere with elk movement where the transmission lines followed the ridge between Midas Creek and Howard Creek. Potential elk movement along the ridge between Miller Creek and Howard Creek could be affected by Alternatives 4D-R and 4E-R. Elk could be discouraged from using these areas during transmission line construction due to increased noise from helicopters and machinery and the presence of humans, but these effects would be short-term. The width of clearing area would not likely be great enough to affect elk movement in this area after the Construction Phase because sufficient cover would be present.

Wildlife Approach Area

The eastern segment of the Alternative 2B transmission line corridor would occur within the wildlife approach area in the Fisher River valley and relatively small segments of all combined mine-transmission line action alternatives would cross the Fisher River valley in the wildlife approach area. The portions of the combined agencies' alternative transmission lines that would parallel US 2 would be located upslope and out of the Fisher River valley, and would not likely affect elk movement in the approach area. Impacts of the combined mine-transmission line action alternatives on elk in the Fisher River valley wildlife approach area are the same as described for transmission line Alternatives B, C-R, D-R, and E-R above.

Elk Winter Range on All Lands

Impacts on elk winter range from the combined mine-transmission line action alternatives on all lands in the analysis area, including private and State lands, would range between 103 acres and 161 acres. Alternatives 3C-R and 4C-R would have the greatest impacts on winter range, while Alternatives 3E-R and 4E-R would have the fewest impacts on winter range. In all combined mine-transmission line action alternatives, direct impacts on winter range would include a reduction in thermal and hiding cover and, once the transmission line corridor was revegetated, an increase in forage habitat. Short-term disturbance impacts in elk winter range from transmission line construction would be minimized by restricting construction during the winter. All combined action alternatives would result in increased road densities on state and private lands. Roads opened or constructed for transmission line access on private land would be gated after transmission line construction, and could result in a reduction of elk security habitat and increased elk mortality if hunting access were allowed. Short-term habitat displacement could occur in the analysis area during transmission line construction as a result of increased road use and helicopter use. State and private lands including the Sedlak Park Substation and loop line, currently have high road densities and overall elk populations would not likely be affected.

Cumulative Effects

Past Actions and the Existing Condition

Past actions are described in section 3.2, *Past and Current Actions,* shown on Figure 50, and listed in Appendix E.

Forest management practices and other human activities (*e.g.,* hunting, wood consumption, and motorized recreation) have had influential cumulative impacts on elk and other big-game security, as well as measurable fluctuations in cover to forage ratios. While natural events, such as wildfires, can result in dramatic and immediate changes to big-game cover, and will continue to do so, it is the indirect effects of forest management that has likely had the greatest impact on big-game habitat in the form of road construction and associated uses. Use of these roads decrease elk and other big-game security (increasing vulnerability or risk of mortality), decrease habitat availability via temporary displacement, and can increase stress levels of resident species. The formulation and adherence to KFP standards for open and total road densities has been and will continue to be an important tool to mitigate the associated cumulative impacts to elk and other big-game. The current conditions of various elk habitat components are displayed in Table 197 and Table 198.

Past forest management has also contributed positively to elk and big-game habitat. Logging and prescribed burning have worked successfully to cycle forest cover through the many periods of succession. Harvest has occurred in the analysis area since the 1950s and resulted in a diversity of age classes and successional stages that provide forage and cover for elk and other big game species. Roads built associated with this harvest activity increased open roads while reducing habitat effectiveness, as well as improving human access and decreasing security. Detailed descriptions of previous vegetation and road management activities are found in section 3.2, *Past and Current Actions*. In unharvested areas, natural disturbances such as wildfire would have resulted in a mosaic of vegetation successional stages providing a diversity of forage or cover habitat. Fire suppression since the early 1900s in some areas has allowed relatively uninterrupted succession to occur resulting in more homogenous stands with greater canopy closure and reduced potential for forage production.

Activities affecting elk habitat have changed in recent years, with a trend toward reduced motorized access as a result of decisions intended to facilitate grizzly bear recovery. This in turn has benefited elk with the resulting increase in habitat effectiveness and secure habitat available for elk. Since the mid-1990s, there has also been a greater use of intermediate harvest methods, which results in both hiding cover and foraging opportunities occurring in close proximity. Prescribed burning has worked successfully to cycle forest cover through the many periods of succession.

Roads constructed in association with timber harvest, mining, and other development have cumulatively reduced elk security habitat and habitat effectiveness in the analysis area. Development of private lands within the analysis area, including commercial timber harvest, land clearing, home construction, and road construction has contributed to increased disturbance of elk and a loss or reduction in quality of foraging and winter habitat, and is expected to continue. Fire suppression has resulted in the encroachment of conifers into foraging habitat and aging of shrub habitat.

Areas previously impacted by special use permits such as mineral material sites (pits quarries, borrow, roadsides), water developments, utility corridors, private land access routes, and outfitter/guide trails/camps, would continue to be present and utilized. The ground disturbance on resources such as elk winter range, habitat effectiveness and cover is described previously for the affected environment and would have no additional impacts. Other public uses such as wildlife viewing, berry picking, firewood gathering, camping, snowmobiling, etc. have negligible impacts on elk given their limited scope (time and space). Infra-structure, such as roads and campgrounds, that facilitate these activities have already been accounted in the description of the affected environment.

Effects of Current and Reasonably Foreseeable Actions

Reasonably foreseeable actions are described in section 3.3, *Reasonably Foreseeable Future Action or Conditions*. Current actions are described in section 3.2, *Past and Current Actions* and shown on Figure 50.

The Miller-West Fisher Vegetation Management Project will occur entirely in the Silverfish PSU and will include intermediate harvest of 1,206 acres, regeneration harvest of about 692 acres, precommercial thinning of 351 acres, and prescribed burning of 2,830 acres of National Forest System lands in the Silverfish PSU. Because of the availability of harvest data, the effects of the Miller-West Fisher Vegetation Management Project can be evaluated quantitatively for cover and forage. Surface impacts from other reasonably foreseeable actions in the Silverfish PSU would be minimal, and would not result in any measurable changes in cover or forage habitat. Cumulative impacts of the Miller-West Fisher Vegetation Management Project on cover-to-forage ratios in MAs 10 and 11 and on percent cover in MAs 15, 16, and 17 are shown in Table 201. Because the mine alternatives would not affect elk habitat in the Silverfish PSU and because the transmission line action alternatives would not change the percent cover to forage in summer range or the percent of thermal cover in winter range, effects on these habitat components are not shown in Table 201.

New roads and access changes for mitigation associated with reasonably foreseeable actions, including the Wayup Mine/Fourth of July Road Access Project, and the Miller-West Fisher Vegetation Management Project, would contribute to cumulative effects on ORD (Table 201). Access changes resulting from Wayup Mine/Fourth of July Road Access Project, Plum Creek activities, the Miller-West Fisher Vegetation Management Project, and other reasonably foreseeable actions would increase ORD to 1.76 mi/mi^2 in MA 12 and 1.1 mi/mi^2 in MAs 15, 16, 17, and 18. ORD in the Silverfish PSU would increase to 0.82 mi/mi^2 as a result of reasonably foreseeable activities. Habitat effectiveness in MA 12 would decrease to 64 percent, habitat effectiveness in MAs 15, 16, 17, 18 would decrease to 59 percent, and habitat effectiveness in the Silverfish PSU would decrease to 66 percent as a result of reasonably foreseeable actions. Habitat Security on the Silverfish PSU would decrease 10 percent to 47 percent.

Road management actions such as road maintenance and administrative use associated with permit administration, data collection and monitoring of National Forest System lands are not likely to affect elk habitat because they generally do not result in vegetation removal. Elk and other large ungulates will typically simply avoid the disturbance area until human activities terminate, which usually comprises of a few hours. These activities include work on existing roads for the Miller-West Fisher Project. This action would not result in a loss of cover because the roads that will be used already exist. Although water restoration projects may temporarily displace elk and other wildlife from a localized area, they typically benefit wildlife in the long-term by increasing security, providing pulses of foraging when seeded, or by stabilizing soils where certain habitat components can remain available.

The Coyote Improvement vegetation management project is in the planning stages and would take place within the Crazy PSU. The project would harvest 240 acres to increase stand resiliency to mountain pine beetles. This project would contribute to open canopy habitat/openings within the analysis area. This habitat component is generally lacking on the landscape and Coyote Improvement project would contribute toward improving its availability within these planning subunits. The transmission line alternatives would contribute openings as well, although they are expected to be maintained longer before natural succession is allowed to occur compared to Coyote Improvement.

Silverbutte Bugs timber sale is in the Silverfish PSU and would be a small project like Coyote. Similar to the timber sales mentioned above, it would contribute some openings/open-canopied habitat within this PSU. If Silverbutte Bugs mainly treats stands already impacted by insects/disease, those stands may already be in an open-canopied condition.

Flower Creek timber sale is in the Treasure PSU and only has minimal overlap with the project with a small amount of the access road for Montanore located within this PSU. Flower Creek timber sale, like the timber sales mentioned above, would contribute openings or open-canopied habitat as well. Approximately 900 acres are proposed for treatment. Due to the minimal overlap, cumulative effects would be minimal.

Actions such as road, trail, campground maintenance and administrative use associated with permit administration, data collection and monitoring of National Forest System lands are not likely to measurably affect elk and other big game species. These species will typically simply avoid the disturbance area until human activities terminate, which usually comprises of a few hours. With population growth and development, it is reasonable to assume that some corresponding increase in human use of National Forest System lands is likely to occur. Recreational activities such as sightseeing, hiking, cross-country skiing, camping, snowmobiling, fishing, and firewood cutting are ongoing and expected to increase over the next 10 years. This increase is likely to be gradual and incremental and tend to be focused on areas along or near roads open to motorized traffic. Elk may, over time, experience more frequent disruption of their daily activities if they are in proximity to roads, although as discussed previously, these areas receive proportionately less use by elk than more secure habitats. Also, any increase in recreation activities are not likely to occur around private lands where most of the activities are located and would not appreciably change the existing condition as elk already tend to avoid open roads.

Activities on private land, such as timber harvest, land clearing, home construction, road construction, and livestock grazing, are likely to continue on private lands within the Silverfish PSU and would likely slightly impact on elk cover and security. Potential effects depend on the magnitude, type and location of developments and include the loss of secure habitat and localized disturbance on elk and other big game species. Private lands occupy 12 percent of the Silverfish PSU and are intermixed with public and corporate/State land. Most recommended guidelines are met on National Forest System Lands within the Silverfish PSU, and development of private lands is expected to have minor cumulative impacts on elk and other big game species within the analysis area over the next 10 years.

No Action Alternative

The Montanore Project No Action alternatives (Alternative 1 and Alternative A) would not contribute to cumulative impacts on elk.

Combined Mine-Transmission Line Action Alternatives

Cumulative impacts of the combined mine-transmission line alternatives, in combination with other reasonably foreseeable actions, on percent elk security habitat, habitat effectiveness, and ORD are shown in Table 201. The mine alternatives would not have any effects on elk in the Silverfish PSU, and would not contribute to cumulative effects.

Cover/Forage

The transmission line action alternatives would not change the percent cover to forage in summer range or the percent of thermal cover in winter range and would not contribute to cumulative changes in these parameters.

All combined mine-transmission line action alternatives, in combination with the Miller-West Fisher Vegetation Management Project, would decrease cover in MAs 10 and 11 by 2 to 4 percent. All transmission line alternatives would include the reallocation of MAs 10 and 11 in a 500-foot corridor along the transmission line to MA 23, which does not have a cover/forage standard. Alternatives 2B, 3E-R, and 4E-R, in combination with the Miller-West Fisher Vegetation Management Project, would not affect cover in MAs 15, 16, and 17, while Alternatives 3C-R, 3D-R, 4C-R, and 4D-R would reduce cover in MAs 15, 16, and 17 by 2 to 3 percent.

Habitat clearing and forest treatments associated with the Montanore Project combined mine-transmission line action alternatives and the Miller-West Fisher Vegetation Management Project provide more forage habitat, which would improve overall habitat conditions in FWP elk HD 104 and the KNF. Given the existing abundant cover, cumulative effects on cover are not likely to adversely affect elk populations in elk HD number 104 or the KNF.

Open Road Density, Security Habitat, and Habitat Effectiveness

As described above, access changes resulting from the Wayup Mine/Fourth of July Road Access Project, Plum Creek activities, the Miller-West Fisher Vegetation Management Project, and other reasonably foreseeable actions would increase ORDs in MA 12 and MAs 15, 16, 17, and 18. During construction, Alternatives 2B, 3C-R, 3D-R, 4C-R, and 4D-R would increase ORD in MAs 15, 16, 17, and 18 to 1.0 mi/mi^2 to 1.2 mi/mi^2. During construction in MA 12, Alternatives 2B, 3C-R, D-R, 4C-R, and 4D-R would increase ORD to 1.45 mi/mi^2 to 1.49 mi/mi^2, while Alternatives 3E-R and 4E-R would increase ORD to 1.80 mi/mi^2. In all combined mine-transmission line action alternatives, ORD in MAs 15, 16, 17, and 18 during transmission line construction would be the same or slightly less than Alternative 1, which includes the effects of other actions only, and would be less than the standard.

During operations, cumulative ORD in MAs 15, 16, 17, and 18 would increase, relative to existing conditions, during operations to 1.0 mi/mi^2 to 1.2 mi/mi^2 for Alternatives 2B, 3C-R, 3E-R, 4C-R, and 4E-R and it would remain the same in Alternatives 3D-R and 4D-R. In all combined mine-transmission line action alternatives, ORD in MAs 15, 16, 17, and 18 during transmission line operations would be the less than the standard. Cumulative ORD in MA 12 during operations would continue to be greater than existing conditions and the standard, ranging from 1.43 mi/mi^2 to 1.44 mi/mi^2.

All combined mine-transmission line action alternatives, in combination with the Wayup Mine/Fourth of July Road Access Project, Plum Creek activities, the Miller-West Fisher Vegetation Management Project, and other reasonably foreseeable actions, would reduce security habitat by 9 to 10 percent during transmission line construction. During construction, habitat effectiveness would be reduced by 8 to 10 percent as a result of cumulative impacts of the combined mine-transmission line action alternatives in combination with the Wayup Mine/Fourth of July Road Access Project, Plum Creek activities, the Miller-West Fisher Vegetation Management Project, and other reasonably foreseeable actions (Table 201). For all combined mine-transmission line action alternatives, percent security habitat during operations would improve relative to the No Mine Alternative, which includes the effects of other reasonably foreseeable actions. As shown in Table 201), the contribution of the Montanore combined mine-transmission line action alternatives to changes in percent habitat effectiveness would not be measurable during operations.

Forage Openings

The combined mine-transmission line alternatives would not create any new openings greater than 40 acres with points greater than 600 feet from cover in the Silverfish PSU, and would not contribute to cumulative increases in forest openings that elk might avoid.

Key Habitat Features

All combined mine-transmission line action alternatives would result in the disturbance of wetlands providing potential wallowing habitat for elk in the Silverfish PSU. The clearing area for the combined mine-transmission line action alternatives would include between 2 and 4 acres of wetlands. Other reasonably foreseeable actions would contribute to losses of wetland habitat; unavoidable impacts on wetlands in all reasonably foreseeable actions would require compensatory mitigation under the Clean Water Act or Executive Order 11990.

Movement Areas

All combined mine-transmission line action alternatives may interfere with elk movement where ridges and drainages were crossed. Disturbance-related impacts would be short-term, and the width of clearing area would not likely be great enough to affect elk movement after the Construction Phase because sufficient cover would be present. Other reasonably foreseeable actions could impede elk movement in specific areas, but KNF riparian standards would minimize activities in riparian areas, and activities on ridgelines would generally be avoided due to steep terrain. While some cumulative effects to elk movement could occur, they would likely to be minimal.

Table 201. Cumulative Effects to Elk Habitat Components on National Forest System Land in the Silverfish PSU by Combined Mine-Transmission Line Alternative.

[1] Effects shown include effects of the Wayup Mine/Fourth of July Road Access Project, Plum Creek activities, the Rock Creek Project, and the Miller-West Fisher Vegetation Management Project. Alternative 1 (No Transmission Line) would not contribute to cumulative effects on ORD.
[2] Const = during mine construction.
[3] Ops = during transmission line operations.
[4] MAs 10 and 11 are managed for big game winter range; all MA 10 and 11 within a 500-foot corridor of the transmission line centerline would be reallocated to MA 23.
[5] Security habitat is calculated by buffering all roads open during the fall (October 15 to November 30) by 0.5 mile. The remaining total area, which may consist of one or more habitat blocks greater than 250 acres, equals security habitat. Security habitat may include State and private lands, but no elk security habitat occurs on private or State land in the analysis area.
[6] Habitat Effectiveness is based on the relationship between open road density and habitat effectiveness, as described in Appendix H of Johnson (2004a).
[7] All MA 12 within a 500-foot corridor of the transmission line centerline would be reallocated to MA 23.
ORD = open road density.
Source: GIS analysis by ERO Resources Corp. using KNF data.

Wildlife Approach Area

The eastern segment of the Alternative 2B transmission line corridor would occur within the wildlife approach area in the Fisher River valley and relatively small segments of all combined mine-transmission line action alternatives would cross the Fisher River valley in the wildlife approach area. The proximity of the Alternative 2B alignment to US 2 would result in a widening of disturbed area and could potentially discourage elk movement within the approach area by decreasing cover. The Miller-West Fisher Vegetation Management Project could also perturb elk movement within the approach area by decreasing cover and contributing to human disturbance. Given that most of the approach area potentially affected by Alternative B and the Miller-West Fisher vegetation Project is generally heavily roaded and has been logged in the past 20 to 30 years, and because of the short-term nature of human-caused disturbance, it is likely that the cumulative effects of the two projects on elk movement within the approach area would be minimal. The portions of the combined agencies' alternative transmission lines that would parallel US 2 would be located upslope and out of the Fisher River valley, and would not likely contribute to any cumulative effects on elk movement in the approach area.

Elk Winter Range on All Lands

All combined mine-transmission line action alternatives, in combination with other reasonably foreseeable actions, especially the Miller-West Fisher Vegetation Management Project, would result in cumulative impacts on elk winter range on all lands in the analysis area, resulting in a reduction of thermal and hiding cover and, once disturbed areas were revegetated, an increase in forage habitat. Cumulative impacts of all combined mine-transmission line action alternatives would be minor due to construction timing restrictions in elk winter range. The combined mine-transmission line action alternatives, in combination with Plum Creek activities, would result in cumulative disturbance to elk on private lands in the analysis area, and could displace of elk away from areas of disturbance. Cumulative disturbance to elk on private lands are expected to be minimal because private lands are generally heavily roaded and elk in these areas may be habituated to higher levels of disturbance than on National Forest System lands.

Cumulative Effects of Plan Amendments for Open Road Density (MA 12)

All action alternatives would reallocate MA 12 lands to MA 23 within a 500-foot corridor designated for the transmission line corridor. Where new or opened roads associated with all action transmission line alternatives would be outside the 500-foot transmission line corridor, a site specific KFP amendment would be required for all action alternatives to allow for exceedance of the MA 12 ORD standard.

Johnson (2006) analyzed the cumulative effects of the KFP amendment for changing the ORD requirements. This analysis looked at post-project changes in ORD, both increases and decreases, and calculated a cumulative change to ORD in MA 12. As of 2006, the cumulative change in available elk habitat was an increase of about 0.16 percent. Since 2006, only six projects have received a project specific amendment for ORD in MA 12, which now total 46 for the KNF (USDA Forest Service 2013b). Of these, four of the projects would have high ORD levels during implementation but would return to the existing condition post-project and would not result in a cumulative change to available elk habitat. One project would improve upon the existing ORD level post-project and ORD would become better than the MA standard.

The transmission line alternatives would decrease the allocation of MA 12 within the Silverfish PSU resulting in less MA 12 acreage with high open road densities. The MA 23 lands resulting from the reallocation have no ORD standard, and after an increase in ORD during the construction and reclamation period, would largely provide similar ORD levels as prior to reallocation. Cumulatively it is expected that available elk habitat on the KNF would be maintained. A measurable change in big game populations would not be expected.

As described under the Affected Environment section, the elk population appears to be increasing which may be due to increased road restrictions and decommission in the past 20 years (USDA Forest Service 2008a). The cumulative effects of past and present land use patterns as well as random natural events have been taken into consideration in this analysis.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. All mine and transmission line alternatives would comply with 36 CFR 228.8.

National Forest Management Act/Kootenai Forest Plan

1. Forestwide Management Direction – KFP II-1 #3, #7, II-2 #12, #17, II-7, 22, 23

#3 – *Maintain a balance of open and closed road… (to) insure big-game habitat security…:* In all combined mine-transmission line alternatives, although during transmission line construction some restricted, impassable/barriered, and temporary roads would be opened and some new access roads would be needed, road access changes to mitigate for impacts on grizzly bear would be implemented. The agencies' alternatives would also include access changes in numerous roads to mitigate for the loss of big game security (Figure 35). In all combined mine-transmission line alternatives, security habitat would return to existing levels following construction, and would be greater than recommended levels during all project phases.

#7 – *Maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species:* Cover to forage ratios in the Silverfish PSU indicate that the proportion of forage habitat is well below recommended levels. Current populations of elk would likely be maintained in all mine-transmission line action alternatives because changes to cover to forage ratios would be 4 percent or less, and because while cover would decrease relative to forage, the Silverfish PSU provides an abundance of cover.

#12 – *Maintain big-game habitat to support the recreational hunting demand for resident big-game species:* Levels of habitat effectiveness and security throughout the PSU would be maintained above recommended guidelines and would provide for habitat conditions maintaining the existing populations of elk for local hunting demand. Overall, road densities, percent security habitat and habitat effectiveness would likely continue to improve through land acquisition associated with grizzly bear mitigation.

#17 – *Use prescribed fire to simulate natural ecological processes… create habitat diversity for wildlife…* None of the alternatives would include prescribed burns.

p.II-7 – Management of elk habitat will provide for a potential habitat carrying capacity, which, by the third decade, is nearly 40 percent greater than present elk numbers. Habitat maintenance to support huntable populations of all other big game species as well as viable population levels of all endemic vertebrate species of wildlife: Elk population and the number of large bulls on the

Forest has been increasing over the past 20 years, probably because of increased road restrictions and decommissioning which has improved elk security on the KNF (USDA Forest Service 2008c). Proposed activities would not permanently decrease security within the analysis area, and overall, security would increase as a result of the grizzly bear mitigation and land acquisition program.

p.II-22, 23 – *Maintenance of viable populations of existing native and desirable non-native vertebrate species, as monitored through indicator species, attained through the maintenance of a diversity of plant communities and habitats*: See #7. above for habitat diversity. Elk are monitored as an indicator species for general forest habitat. Their occurrence and estimation of population is monitored through District observations, FWP surveys, and KNF Monitoring and Evaluation Reports.

2. Applicable Management Area Direction (MAs 10, 11, 12, 15, 17) –KFP III-39, 44/45, 48/49/51, 65, and 75.

Objectives of the proposed mine-transmission line action alternatives are to facilitate mine development. Mine-transmission line action alternatives would include the re-allocation of MA 10, MA 11 and MA 12 lands in a 500-foot corridor along the transmission line to MA 23. As explained below, outside of this corridor a KFP amendment to allow for increased ORD in MA 12 would be necessary for all combined mine-transmission line alternatives.

MA 10 (Big Game Winter Range) – *Maintain or enhance the habitat effectiveness for winter use by big game species through cover/forage ratios, prescribed fire, and maintenance of wildlife movement patterns:* All transmission line alternatives would include the reallocation of MAs 10 and 11 in a 500-foot corridor along the transmission line to MA 23, which does not have a cover/forage standard. Outside of this corridor, changes to cover to forage ratios would be 2 percent or less for all combined mine-transmission line alternatives and the Silverfish PSU provides an abundance of cover. After transmission line construction disturbed areas would be allowed to establish naturally as grassland or shrubland. Once vegetation is re-established, areas of winter range would provide forage habitat during the life of the mine. Weed control and other BMPs would be implemented. After the transmission line was removed, and vegetation was re-established, forage would be provided on the winter range. All combined mine-transmission line action alternatives would decrease both percent elk security and habitat effectiveness in the Silverfish PSU, however both measurement criteria would remain better than the recommended minimum levels.

MA 11 (Timber/Big Game Winter Range) – *Maintain or enhance the winter range habitat effectiveness for big game species (while also achieving timber and visual goals) through prescribed fire, maintenance of wildlife movement patterns/corridors, management of key habitat components as riparian areas, and utilizing harvest to achieve desired cover/forage ratios, a variety of seral stages, and maximization of edge effect in units generally not exceeding 40 acres:* See description for MA 10 above.

MA 12 (Timber/Big Game Summer Range) – *Maintain or enhance non-winter big game habitat (while also achieving timber goals) through habitat diversity, maximization of edge effect in units generally not exceeding 40 acres, maintaining hiding cover between openings, management of key habitat components as riparian areas, managing open roads to no more than ¾ miles per square mile:* All combined mine-transmission line alternatives would include the reallocation of

MA 12 in a 500-foot corridor along the transmission line to MA 23. The reallocation would be for the duration of the proposed Montanore Project. Where new or opened roads associated with the combined mine-transmission line alternatives would be outside the 500-foot transmission line corridor, a site specific KFP amendment would be required to allow for exceedance of the MA 12 ORD standard of 0.75 mi/mi^2. The KFP amendment to in the MA 12 ORD standard would be required for the life of the project for all Action Alternatives. High levels of security habitat and HE would be maintained in the Silverfish PSU as well as the maintenance of timbered movement areas between openings. All key habitat components have been identified and maintained under all alternatives.

MA 15 (Timber Production) - *Produce timber using various standard silvicultural practices while providing for other resource values such as wildlife, including big game, through maintenance of habitat effectiveness and security by limiting ORD to a maximum of 3 miles per square mile and management of key habitat components, such as riparian areas:* For all combined mine-transmission line alternatives, ORD would remain less than the standard for all project phases. None of the combined mine-transmission line alternatives would increase ORD in MAs 15, 16, 17, and 18 during operations, and it would decrease by 0.2 mi/mi^2 in Alternatives 3D-R and 4D-R. High levels of security habitat and HE would be maintained in the Silverfish PSU as well as the maintenance of timbered movement areas between openings. All key habitat components have been identified and maintained under all alternatives.

MA 16 (Timber with Viewing) - *Produce timber while providing for a pleasing view. Manage wildlife habitat to provide for viable populations of existing native species, including big game, through maintenance of habitat effectiveness and security by limiting ORD to a maximum of 3 miles per square mile and management of key habitat components, such as riparian areas:* See MA 15 above.

MA 17 (Viewing with Timber) - *Provide landscapes that are pleasing to the viewer, while producing a level of timber production that is compatible with visual resource protection. Manage wildlife habitat to provide for viable populations of existing native wildlife species, including big game, through maintenance of habitat effectiveness and security by limiting ORD to a maximum of 3 miles per square mile and management of key habitat components, such as riparian areas:* MA 17 does not occur in the analysis area.

MA 18 (Regeneration Problem Areas; Steep Slopes) – *Maintain existing vegetation (future timber production) and viable populations of existing native wildlife species, including big game, through maintenance of habitat effectiveness and security by limiting ORD to a maximum of 3 miles per square mile and management of key habitat components, such as riparian areas:* See MA 15 above.

Forest Service Management Indicator Species Statement of Findings

KFP direction is to “maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species,… in sufficient quality and quantity to maintain viable populations” (KFP Vol. 1, II-1 #7). Based on the elk analysis and the KNF Conservation Plan (Johnson 2004a), all combined mine-transmission line action alternatives should provide general forest species habitat with sufficient quality and quantity of the diverse age classes of vegetation needed for viable populations. In all combined mine-transmission line alternatives, sufficient general forest habitat should be available; the populations of species using that habitat should remain viable.

Based on the elk analysis of general forest habitat indicators and the KNF Conservation Plan (Johnson 2004a), sufficient quality and quantity of diverse habitat types and age classes of vegetation are available and would continue to be available to support elk populations in the Silverfish PSU. The mine-transmission line action alternatives would decrease cover, increase displacement, decrease security, decrease habitat effectiveness and increase open road densities during construction. All transmission line action alternatives would decrease both percent elk security and habitat effectiveness in the Silverfish PSU; both measurement criteria would remain better than the recommended minimum levels. Overall, the level of security and habitat effectiveness for elk would increase as a result of land acquisition associated with the grizzly bear mitigation. A diversity of habitat types and successional stages would also be maintained within the PSU.

State Requirements

Alternatives 3 and 4 would comply with the MMRA regarding disturbed lands being reclaimed to a post-mining land use with stability and utility comparable to that of the pre-mining landscape. Draft findings regarding compliance with MFSA requirements are discussed in the Summary, beginning on p. S-53. Hunting is managed by FWP. Proposed actions would not prevent the state from continuing to manage this species as a harvestable population.

The analysis area is located in the Lower Clark Fork and Salish Elk Management Units identified in the FWP Statewide Elk Management Plan. All of the agencies' combined mine-transmission line alternatives are consistent with the document because they would maintain high levels of security habitat and habitat effectiveness. In addition, based on helicopter construction timing described in section 2.5.7, *Mitigation Plans*, in the agencies' alternatives, no transmission line construction activities would occur during hunting season on National Forest System lands.

3.25.3.3 White-tailed Deer

The white-tailed deer was selected as the general forest indicator for the Crazy PSU. As described previously in section 3.25.3.2, *Elk*, this selection was based on management emphasis ratings, KFP direction, the biological potential of the area, state wildlife management objectives, public comments during scoping, information contained within the KNF Conservation Plan (Johnson 2004a), and site-specific knowledge of deer and elk use in the Crazy and Silverfish PSUs.

3.25.3.3.1 Analysis Area and Methods

White-tailed deer population ecology, biology, habitat description, and relationships identified by research are described in Baty (1995), Mundinger (1981), Morgan (1993), Lyon (1966), Thomas (1979), and Mackie *et al.* (1998). White-tailed deer population and harvest data come primarily from FWP. Additional information is provided by recent District wildlife observation records and KNF historical data (NRIS Wildlife).

The analysis area for evaluating direct, indirect and cumulative effects on individuals and their habitat on National Forest System lands is the Crazy PSU, because activities in these areas could result in disturbance and displacement effects to white-tailed deer (Figure 89). White-tailed deer emphasis areas were defined by the PSU, although adjacent planning areas were also considered for effects. White- tailed deer have home ranges that include both winter and summer use areas that could extend beyond the Crazy PSU. The PSU is large enough to account for effects on these various components of white-tailed deer habitat and use in this area. Connectivity and movement within home ranges could be impacted by the proposed activities as well as activities in adjacent

PSUs. To evaluate potential direct, indirect and cumulative impacts of the transmission line on white-tailed deer on private and State land, the analysis area includes all land within a corridor 1 mile on each side of the alternative transmission line alignments. The boundaries for determination of population trend and contribution toward population viability are the FWP hunting districts (HD) 103 and 104 and the KNF, respectively.

Data sources used in this analysis include FWP hunting and population data, research, and plans; District vegetation layers; INFRA roads layers; TSMRS data; Summerfield (1991); and field surveys by District biologists and data collection crews. Indicators used to assess effects on white-tailed deer in the KNF are cover/forage ratios, forage openings, ORD, movement areas, and key habitat features. These indicators are described below.

Impacts to white-tailed deer on private and State land from the transmission line alternatives were evaluated based on FWP winter habitat mapping (Figure 89); FWP hunting and population data, research, and plans; KNF and FWP information on wildlife linkage areas; and mapping of broad vegetation types shown on section 3.23, *Wetlands and Other Waters of the U.S.*

Cover/Forage Ratios

Cover and forage are defined in section 3.25.3.2, *Elk*. Effects of the alternatives are evaluated based on cover/forage ratios for summer and winter range; percent cover for combined MAs 15, 16, and 17; and percent thermal cover on winter range (MAs 10 and 11) in the Crazy PSU. MAs 10 and 11 were delineated for the KFP and do not entirely overlap with white-tailed deer winter range mapped by FWP (Figure 89). MA designations, goals, and standards are described in detail in section 3.15, *Land Use*. To avoid confusion with FWP winter range, for impacts evaluated on National Forest System land, winter range is referred to as MAs 10 and 11. The KFP recommends a cover/forage ratio for white-tailed deer of 70 percent to 30 percent for MAs 10 and 11 combined. Summerfield (1991) recommends a cover of 70 percent on winter and 60 percent on summer range (for all MAs not managed for deer winter range). On white-tailed deer winter range, the cover should be at least 50 percent thermal cover. Summer range cover may be in any combination of hiding and thermal cover (Ibid.). The KFP guideline for hiding and thermal cover on MAs 15, 16, and 17 combined for white-tail deer is greater than 30 percent. MAs 15, 16, and 17 are managed for timber production and do not necessarily correspond to areas of seasonal white-tailed deer use.

Open Road Densities

Effects of roads on white-tailed deer are not well documented. White-tailed deer have smaller home ranges than elk, and may be less likely to avoid roads than elk (Lyon 1979), especially where cover is dense. Roads may increase white-tailed deer vulnerability to hunting season mortality by facilitating hunter access and eliminating refugia (Idaho Department of Fish and Game 2004). KFP standards for ORD are the same for white-tailed deer as described for elk.

Forage Openings

For white-tailed deer, the KFP recommends avoiding the creation of openings greater than 20 acres between areas of cover in MAs 11 and 12. MA 12 is managed to enhance big game non-winter habitat. In MA 10, timber is generally only harvested to maintain or enhance big game winter range, and opening size is minimized. Summerfield (1991) recommends that the opening size be the same as the standard for grizzly bear (a maximum of 600 feet to cover from any point inside an opening). TSMRS forage openings are identified through TSMRS database queries to determine type and age of past harvest. For this analysis, effects of forest openings on deer are evaluated based on the regeneration harvest greater than 20 acres occurring after 1986.

Movement Areas

For white-tailed deer, the corridor of thermal cover between openings that do not provide thermal cover in winter range should be at least 600 feet wide or as wide as the opening, whichever is greater (Summerfield 1991). In the KNF, movement corridors along riparian areas and ridges are especially important for white-tailed deer. The analysis of impacts to movement corridors is based on District GIS mapping of thermal cover in winter range and riparian areas and is available in the Project record.

Key Habitat Features

Moist environments are important to white-tailed deer, especially in late summer to early fall, providing water and high-quality forage and allowing regulation of body temperature (Idaho Department of Fish and Game 2004). Effects of the alternatives on key habitat features will be evaluated based on the acres of wetlands potentially impacted. KFP standards for MAs 11 and 12 include avoidance of wallows, wet meadows and bogs when constructing roads. INFS standards for RHCAs, discussed in detail in section 3.6, *Aquatic Life and Fisheries*, provide additional protection of wallows, wet meadows, and bogs that occur in riparian areas.

Alternative Mitigation Measures

MMC's proposed grizzly bear mitigation plan includes an access change on NFS road #4724 from April 1 to June 30 and a yearlong access change on a segment of NFS road #4784. Although the seasonal closure on Road #4724 would benefit deer by restricting motorized access during the spring, it would not change the open status of the road. NFS road #4784 was proposed for an access change previously by the Rock Creek Project and the agencies do not consider it as mitigation in the analysis for direct effects of Alternative 2B. Because of NFS road #4784 was included in the Rock Creek Project mitigation, the agencies did not propose any change to NFS road #4784 as part of the agencies' alternatives. The agencies action alternatives also considered road #4784 open for the analysis of direct effects on ORD.

Following consultation with the USFWS on the grizzly bear mitigation plan, the KNF decided the access change on NFS road #4784 would be implemented before the Evaluation Phase by all the action alternatives if the road closure was not already implemented as part of the Rock Creek Project mitigation. The access change is discussed qualitatively as a potential direct effect of the Montanore Project. The #4784 access change remains attributable to the Rock Creek Project and improvements to ORD are disclosed in the cumulative effects analysis.

The agencies' alternatives would include additional yearlong access changes through the installation of barriers or gates in several roads to mitigate for the loss of big game security and impacts (Table 28 and Table 29 and Figure 35). These road access changes are taken into account in road density calculations.

Additional road access changes may also occur on land acquired as part of the grizzly bear mitigation proposed by MMC or the agencies (see mitigation plan descriptions in sections 2.4, *Alternative 2- MMC's Proposed Mine*, and section 2.5, *Alternative 3—Agency Mitigated Poorman Impoundment Alternative*). Road density calculations do not take into account the effect of land acquisition requirement for grizzly bear mitigation.

Other mitigation measures incorporated into MMC's or the agencies' alternatives that could benefit white-tailed deer include winter construction timing restrictions in white-tailed deer winter range, prohibiting employees from carrying firearms, and monitoring road-killed animals along mine access roads to determine if improved access resulted in increased wildlife mortality.

All alternatives would include the reallocation of MAs 15, 16, 17, and 18 in the mine permit area to MA 31. Transmission line Alternatives D-R and E-R would include the reallocation of MA 12 in a 500-foot corridor along the transmission line to MA 23. Road density calculations take into account MA reallocation.

3.25.3.3.2 Affected Environment

The Crazy PSU is within HD 104. The eastern portions of the transmission line alternatives would occur in HD 103. The FWP evaluates deer population composition and trends based on total deer, fawn/doe ratios, and buck/doe ratios observed during sampling surveys of a portion of the HD referred to as trend areas, harvest data, and hunter effort data (Brown, pers. comm. 2008). Based on FWP data, the KNF's 2007 Monitoring and Evaluation Report (USDA Forest Service 2008c) concluded that white-tailed deer are the most abundant and widespread big game animal in the KNF, and that the white-tailed deer population in the KNF is steadily increasing. The average number of white-tailed deer observed in the trend area for HD 104 from 1996 to 2013 was 276 deer. An average of 36 fawns was observed for every 100 adults (FWP 2013b). In HD 103, an average of 242 adults and 33 fawns per 100 adults was observed from 1996 to 2013 (FWP 2013b). Based on harvest data, white-tailed deer populations declined in northwest Montana from 2006 to 2009, but after the mild winters of 2010 and 2011 appear to be recovering (FWP 2013b, 2013c).

Cover/Forage

Currently, white-tailed deer summer range in the Crazy PSU is comprised of 96 percent cover and 4 percent forage habitat, while MAs 10 and 11 are comprised of 82 percent cover and 18 percent forage habitat (Table 202). The proportion of thermal cover in MAs 10 and 11 is 9 percent. In comparison to the 50 percent minimum recommended by Summerfield (1991), thermal cover is not adequately provided in the Crazy PSU in MAs 10 and 11. MAs 15, 16, and 17 in the Crazy PSU consist of 85 percent thermal and hiding cover combined, which is greater than the recommended 30 percent minimum. MAs 15, 16, 17, and 18 have a limited distribution in the Crazy PSU (Figure 89). Cover to forage ratios in the Crazy PSU indicate that while cover is abundant, thermal cover and forage habitat may be lacking in the Crazy PSU. Forage habitat is underestimated because white-tailed deer will forage underneath forest canopies and in harvested areas currently mapped as cover.

Most forage habitat occurs in lower elevation areas of the Little Cherry Creek drainage and the mouths of its tributaries, or in isolated patches of past disturbance. Most past harvest areas have recovered to the point they are no longer considered openings and contribute to the high cover to forage ratio in the PSU. Historically, wildfire would create a mosaic of successional stages and result in vegetative diversity in this area. In contrast, fire suppression and past timber management has resulted in a trend toward homogenous stand composition and structure consisting of high density stands of shade-tolerant species (see section 3.22, *Vegetation*) that reduce the presence and productivity of understory forage species. In summary, the PSU is currently outside the desired conditions for white-tailed deer and other big game species with high cover and limited forage availability.

Open Road Density

The Crazy PSU contains 93 acres of allocated summer range (MA 12) (Figure 89). Current ORD in the Crazy PSU are 5.27 mi/mi^2 in MA 12, and 4.3 mi/mi^2 in MAs 15, 16, 17, and 18. Road density standards are not met for either MA 12 or MAs 15, 16, 17, and 18. ORD worse than the standard may increase mortality during hunting season by facilitating hunter access (Idaho Department of Fish and Game 2004).

Forage Openings

Recently, created forage openings in MAs 11 and 12 range from less than 1 acre to 320 acres. The Crazy PSU contains six openings greater than 20 acres in MAs 11 and 12. Of the six openings, five have points greater than 600 feet from cover. The distance to cover may discourage white-tailed deer from foraging in these openings.

Movement Areas

Movement corridors along drainage bottoms and ridgetops are especially important for many wildlife species; most of these areas or travel ways are intact. Portions of private land along Libby Creek may lack suitable cover, especially where timber harvests have occurred, affecting the ability of some species to move freely or securely through these areas.

Key Habitat Features

Wetland and riparian areas are described in section 3.23, *Wetlands and Other Waters of the U.S.* About 172 acres of wetlands occur in the Crazy PSU.

Impacts to White-tailed Deer on State or Private Lands

As shown on Figure 89, only a small portion of white-tailed deer winter range occurs in the Crazy PSU, along the lower reaches of Bear Creek. White-tailed deer winter range potentially affected by the transmission line alternatives occurs in the Fisher, West Fisher, and Miller creek corridors. The majority of state and private lands has been harvested for timber, limiting the availability of thermal cover, and currently has high road densities.

A wildlife approach area important to white-tailed deer has been identified in the Fisher River valley between the Barren Peak and Teeters Peak areas to the west of US 2 and the Kenelty Mountain and Fritz Mountain areas to the east of US 2 (see Project record). A detailed description of this wildlife approach area is provided in the elk analysis.

3.25.3.3.3 Environmental Consequences

Impacts on white-tailed deer habitat and open road densities in the Crazy PSU from the various project features of the mine, transmission line, and combined mine-transmission line alternatives are shown in Table 202, Table 203, and Table 204, and are described in the following subsections.

Table 202. Impacts on White-tailed Deer Habitat on National Forest System Land in the Crazy PSU by Mine Alternative.

Habitat Component	[1] No Mine/ Existing Conditions	[2] MMC's Proposed Mine	[3] Agency Mitigated Poorman Impoundment Alternative	[4] Agency Mitigated Little Cherry Creek Impoundment Alternative
Percent Cover/forage Summer Range[1] Guide is 60/40	96/4	92/8	93/7	93/7
Percent Cover/forage in MAs 10 and 11 Standard is 70/30	82/18	82/18	82/18	82/18
Percent Thermal Cover in MAs 10 and 11 Guide is >50	9	9	9	9
Percent Cover in MAs 15, 16, and 17 Guide is >30	85	82	84	82
ORD in MA 12 (mi/mi^2) Standard is <0.75[2]	5.27	5.27	5.27	5.27
ORD in MAs 15, 16, 17, and 18 (mi/mi^2) Standard is <3.0[2]	4.3	4.6	3.8	3.8

Key Habitat Features Potentially Affected (acres)[3]	NA	40	13	40
# Movement Areas Affected[4]	NA	3	3	4

NA = Does not apply.
Impacts on white-tailed deer habitat would be the same for the Construction and Operations Phases.
[1] White-tailed deer summer range includes all MAs except MAs 10 and 11. MA designations, goals, and standards are described in detail in section 3.15, *Land Use*.
[2] All MA 15, 16, 17, and 18 in the mine alternative permit area would be reallocated to MA 31. MA reallocation was taken into account in road density calculations.
[3] Key habitat features, such as bogs and wet meadows, are represented by wetlands, as described in section 3.23, *Wetlands and Other Waters of the U.S.* Values shown are wetlands and streams directly affected from Table 184 and indirectly affected discussed in section 3.23.4.
[4] Movement areas are represented by ridgelines of third order or larger drainages and riparian areas.
Source: GIS analysis by ERO Resources Corp. using KNF data.

Alternative 1 – No Mine

Alternative 1 would not have direct impacts on white-tailed deer or their habitat. Over time, with continued fire suppression and lack of active forest management, indirect effects of this alternative would include a continued trend toward later successional habitats. Forage habitat would decrease over time unless harvest or other stochastic events, such as a wildfire or windstorm, creating additional forage. Large-scale fires could potentially occur in the Crazy PSU. Although vegetative succession would reduce forage openings over time, openings created following large fires would likely be relatively large, with long distances between hiding cover. Until hiding cover develops (about 15 to 20 years, depending on site conditions), individual animals may be more vulnerable to predation and hunting mortality in areas where large openings develop following wildfire. Introduced species that are often unpalatable to deer, would continue to spread in the analysis area, displacing native forage species. Current KNF, state, and local weed management programs Forest Service, state, and county-wide noxious weed management practices would continue to reduce noxious weed infestations. The white-tailed deer population in the KNF is expected to continue to steadily increase.

Alternative 2 – MMC's Proposed Mine

Cover/Forage

Alternative 2 would reduce the percent of cover habitat relative to forage habitat by 4 percent to 92 percent in summer range, moving the cover-to-forage ratios toward the KFP-recommended conditions, while cover habitat relative to forage in winter MAs 10 and 11 would not change (Table 202). Most areas disturbed as a result of Alternative 2 would not be available as foraging habitat until after mine closure and reclamation. Some areas would be reclaimed during operations and would provide foraging habitat once vegetation was established. In the long term, after reclamation success criteria are achieved, areas disturbed by Alternative 2 would provide forage for white-tailed deer, thereby moving toward KFP objectives for forage habitat. The proportion of thermal cover in MAs 10 and 11 would not change as a result of Alternative 2 and would continue to be less than the desired minimum. Percent cover in MAs 15, 16, and 17 in the Crazy PSU would decrease 3 percent, but would continue to be greater than the 30 percent KFP guideline minimum.

Open Road Density

Alternative 2 would not change ORD in MA 12 and would continue to exceed standards in the Crazy PSU (Table 202) requiring a site specific KFP amendment. Alternative 2 would increase ORD in MAs 15, 16, 17, and 18 in the Crazy PSU, where standards are not currently met, to 4.6 mi/mi^2. Where new or opened roads associated with Alternative 2 would be outside the permit area, a KFP amendment to allow for increased ORD in MAs 15, 16, 17, would be necessary. Specifically, the KFP amendment for increases in ORD would apply to MAs 16 and 17 in sections 14, 15, and 24 in T28N, R31W, and sections 18 and 19 in T28N, R30W.

Overall, road densities would likely improve through MMC's proposed land acquisition for grizzly bear mitigation, as described in section 2.5.6, *Mitigation Plans*. Acquired parcels would be managed for grizzly bear use in perpetuity, and could decrease road densities where roads could be gated or barriered, thereby benefitting white-tailed deer.

Widening, improvement, and yearlong access of the Bear Creek Road would lead to increased vehicle volumes and speed. Estimates of increased annual traffic volume range from 187 percent to 234 percent (Table 172 in section 3.21, *Transportation*). The increase in traffic in Alternative 2 would substantially increase the risk of increased deer mortality on the access road. MMC would limit concentrate haulage to daylight hours during the day shift (0800 to 1630), which would minimize vehicular-deer collisions during the early morning, evening and night time-periods. MMC would provide transportation to employees using buses, vans, and pickup trucks thereby limiting the use of personal vehicles. MMC would report road-killed animals to the FWP as soon as road-killed animals were observed. The FWP would either remove road-killed animals or direct MMC how to dispose of them. When the mill ceased operations in the Closure Phase, mine traffic volume would be substantially less than shown in Table 172 in section 3.21, *Transportation*. Future traffic volume when all activities at the mine are completed in the Post-Closure Phase would be higher than in Alternative 1 because of reconstruction of Bear Creek Road and loss of the Little Cherry Loop Road beneath the impoundment. Mortality risk to white-tailed deer would decrease on the Bear Creek Road compared to operations, but the permanently improved road conditions (increased road width, improved sight distance, paving) and higher traffic speeds would result in a permanently higher deer mortality risk compared to pre-mine conditions. At mine closure, all new roads (except the Bear Creek access road) constructed for the project would be reclaimed, which would include grading to match the adjacent topography and obliterating the road prism. After reclamation success criteria are achieved, areas disturbed by road use would provide forage for the white-tailed deer.

Forage Openings

Alternative 2 would create one opening greater than 20 acres in MA 11 along the Bear Creek Road near US 2. Effects on white-tailed deer of this new opening would likely be minimal because no point would be more than 600 feet to cover, and due to its proximity to US 2 and private property. The loss in forage capacity may impact individual white-tailed deer in the short term, until disturbed areas were successfully revegetated.

Movement Areas

Alternative 2 may affect potential white-tailed deer movement corridors in the Little Cherry, Poorman, and Ramsey creek drainages where the tailings impoundment, plant site, and LAD Areas would be constructed, and where other mine-related activities would occur. Facilities associated with Alternative 2 would not occur on ridgetops and would not likely directly interfere with white-tailed deer movement in these areas. Individual animals may have to adjust their localized movement patterns, but no movement barriers would be created by Alternative 2.

KFP standards for MAs 11 and 12 include avoidance of wallows, wet meadows and bogs when constructing roads. INFS standards for RHCAs, discussed in detail in section 3.6, *Aquatic Life and Fisheries*, provide additional protection of wallows, wet meadows, and bogs that occur in riparian areas.

Key Habitat Features

About 39 acres of wetlands providing water and high-quality forage would be impacted by Alternative 2 in the Crazy PSU. An additional 3 acres or more may be affected by a pumpback well system, if installed at the impoundment site. The feasibility of MMC's proposed Wetland Mitigation Plan to replace the lost functions of all potentially affected wetlands is uncertain. MMC's plan is conceptual and would be refined during the 404 permitting process. MMC did not update its mitigation plan for Alternative 2 to reflect new wetland and stream mitigation regulations and procedures. Section 3.23, *Wetlands and other Waters of the U.S.*, discusses proposed wetland mitigation in more detail.

Mine Water Management

MMC would store mine, adit, or tailings water at the Ramsey Plant Site, a surge pond at the LAD Areas, and the tailings impoundment. The metals in the tailings water would be similar to what is found at the Troy Mine decant ponds (see Table 120 in the *Water Quality* section), where adverse effects on wildlife have not been observed (USDA Forest Service and DEQ 2012). Concentrations of metals in mine and adit water, which would be stored in mine/yard pond at the Ramsey Plant Site and in a surge pond at the LAD Areas, would be lower than tailings water (see Table 120 in the *Water Quality* section). The Ramsey Plant Site would be fenced, restricting deer access.

Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Cover/Forage

Impacts of Alternative 3 on cover-to-forage ratios would be similar to Alternative 2 except that in Alternative 3, cover relative to forage habitat would be reduced by 3 percent to 93 percent in summer range, and the percent cover in MAs 15, 16, and 17 in the Crazy PSU would be 1 percent less than existing conditions (Table 202).

Open Road Density

Alternative 3 would not affect ORD in MA 12, but would improve ORD in MAs 15, 16, 17, and 18 to 3.8 mi/mi^2 (Table 202). ORD would continue to be worse than standards in MA 12 and MAs 15, 16, 17, and 18 in the Crazy PSU. Because ORD would decrease (improve), a KFP amendment to increase ORD would not be necessary except in MA 12.

Overall, road densities would likely improve through the agencies' proposed land acquisition requirement for grizzly bear mitigation, as described in section 2.5.7, *Mitigation Plans*. Acquired parcels would be managed for grizzly bear use in perpetuity, and may decrease road densities where roads could be gated or barriered, thereby benefitting white-tailed deer. The effect of increased traffic on the Bear Creek Road would be the same as Alternative 2, except that in Alternative 3, MMC would remove big game animals killed by any vehicles daily from road rights-of-way within the permit area and along roadways used for access or hauling ore for the life of the mine and monitor the number of big game animals killed by vehicle collisions on these roads and report findings annually. Highway safety signs such as "Caution – Truck Traffic" would help slow public traffic speeds in anticipation of meeting oncoming trucks. Staging shipments of supplies in a general location prior to delivery to the mine site would reduce traffic and deer mortality risk.

Forage Openings

The effect of new openings created by Alternative 3 would be the same as Alternative 2.

Movement Areas

Alternative 3 may affect potential white-tailed deer movement corridors in the Little Cherry, Poorman, and Libby creek drainages where the tailings impoundment and plant site would be constructed, and where other mine-related activities would occur. Alternative 3 would affect fewer riparian corridors than Alternative 2 because disturbance from the plant and adits would be concentrated in Libby Creek. Also, the Alternative 3 impoundment would occupy less of the Little Cherry Creek riparian corridor than the Alternative 2 impoundment. Facilities associated with Alternative 3 would not occur on ridgetops and would not directly interfere with white-tailed deer movement in these areas. Individual animals may have to adjust their localized movement patterns, but no movement barriers would be created by Alternative 3.

Key Habitat Features

About 13 acres of wetlands providing water and high-quality forage would be directly affected by Alternative 3 in the Crazy PSU; an additional 16 acres may be affected by a pumpback well system at the tailings impoundment (Table 202). Impacts on wetlands would be mitigated through implementation of the agencies' Wetland Mitigation Plan, which would have a greater likelihood of replacing lost functions than the Alternative 2 Wetland Mitigation Plan.

Mine Water Management

Water management in Alternatives 3 and 4 would reduce the risk to wildlife from contaminant uptake from storage of mine, adit, and tailings water. All mine and adit water would be treated and discharged at the Libby Adit Water Treatment Plant and not stored in ponds. The LAD Areas would not be used and the surge ponds would not pose a risk to white-tailed deer. Tailings water quality would have lower metal concentrations than in Alternative 2; the factors leading to lower metal concentrations in tailings water quality in Alternatives 3 and 4 are discussed in section 3.13, *Water Quality*, p. 674.

Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

The effects of Alternative 4 on road density, forage openings, and movement areas would be the same as Alternative 3.

Cover/Forage

Impacts of Alternative 4 on cover-to-forage ratios for summer range and MAs 10 and 11 would be the same as Alternative 3, except that percent cover in MAs 15, 16, and 17 in the Crazy PSU would decrease by 3 percent to 82 percent (Table 202).

Key Habitat Features

About 43 acres of wetlands providing water and high-quality forage would be directly or indirectly affected by Alternative 4 in the Crazy PSU (Table 202). Impacts on wetlands would be mitigated through implementation of the agencies' Wetland Mitigation Plan, which would have a greater likelihood of replacing lost functions than the Alternative 2 Wetland Mitigation Plan.

Alternative A – No Transmission Line

Alternative A would not have direct impacts on white-tailed deer or their habitat. The effects of Alternative A on deer would be the same as Alternative 1.

Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

Cover/Forage

Alternative B would not change cover relative to forage habitat in summer range or MAs 10 and 11, percent thermal cover in MAs 10 and 11, or percent cover in MAs 15, 16, and 17 in the Crazy PSU (Table 203). The proportion of thermal cover in MAs 10 and 11 would continue to be below minimum recommended levels. Percent cover in MAs 15, 16, and 17 in the Crazy PSU would continue to meet the 30 percent recommended level. All disturbed areas, such as access roads, pulling and tensioning sites, and transmission line clearing areas, would be seeded with grass and shrub species after transmission line construction. Areas where trees were trimmed, but otherwise not disturbed, would be allowed to establish naturally as grassland or shrubland. Once vegetation is re-established, disturbed areas of winter range would provide additional forage habitat as forage species become established, thereby moving white-tailed deer habitat conditions in the Crazy PSU toward KFP objectives. Roads built for the installation of the transmission line would be redisturbed during line decommissioning. After the transmission line was removed, all newly constructed roads would be bladed, contoured, and seeded. Once vegetation re-established, redisturbed areas would provide forage habitat.

Alternative B would increase the spread and establishment of noxious weeds and other introduced species associated with surface disturbance. Alternative B would have the largest area of surface disturbance associated with new or upgraded road construction and timber clearing of all transmission line alternatives, but would have the least area of vegetation clearing. Surface disturbances and continued road use would increase the risk of spread of noxious weeds and other introduced species that are unpalatable to white-tailed deer. New roads would be reseeded as an interim measure, but used for maintenance activities, as necessary.

Open Road Density

During Alternative B line construction, ORD in the Crazy PSU would decrease in MA 12 to 4.93 mi/mi^2, due to road access changes, and would increase to 4.7 mi/mi^2 in MAs 15, 16, 17, and 18 (Table 204). ORD in MAs 15, 16, 17, and 18 in the Crazy PSU would be 0.1 mi/mi^2 worse than existing densities during transmission line operations. No areas of MA 12 would be reallocated to MA 23 because no MA 12 would occur in the 500-foot transmission line corridor. In Alternative B, a KFP amendment to increase ORD in MAs 15, 16, 17, and 18 would be needed. Specifically, the KFP amendment for increases in ORD would apply to MAs 15 and 16 in sections 7, 8, 17, and 18 in T27N, R30W, and sections 1, 2, and 12 in T27N, R31W. ORD in MA 12 would continue to be worse than the KFP standard, but because it would decrease, a KFP amendment to increase ORD in MA 12 would not be necessary.

Although the new road prism in Alternative B would remain during transmission line operations, roads opened or constructed for transmission line access would be gated or barriered on National Forest System land after transmission line construction. New roads constructed for Alternative B could improve access for hunters on foot. During the final Closure Phase following mine closure, the transmission line would be removed, roads reclaimed, trees along the line allowed to grow, and all disturbed areas revegetated.

Helicopter line-stringing, which would last about 10 days, could contribute to short-term displacement of individual deer from the transmission line corridor. Similar effects could occur from other transmission line construction activities in areas where helicopters were not used, and would be more extensive for Alternative B than the agencies' alternatives. Except for annual inspection and infrequent maintenance operations, helicopter use and other construction activities would cease after transmission line construction until decommissioning. Helicopter use and other activities associated with decommissioning would cause similar disturbances.

In Alternative B, no construction would occur during winter (assumed to be December 1 to April 30) on winter range, and no motorized activity would occur from April 1 to June 15 in bear habitat in the Miller Creek and Midas Creek drainages. The winter and spring construction timing restrictions would reduce displacement effects. Overall, effects of helicopter activity on white-tailed deer would be minimal because sufficient habitat would be available for any deer displaced due to short-term disturbance, and because construction timing restrictions would reduce the extent of potential displacement effects.

Forage Openings

No additional openings in forest cover greater than 20 acres would be created by the Alternative B in MAs 10 and 11 would be the transmission line clearing area.

Source: GIS analysis by ERO Resources Corp. using KNF data.

Key Habitat Features

About 4 acres of wetlands providing water and high-quality forage would be within the clearing area of Alternative B in the Crazy PSU (Table 203). Direct effects to wetlands are expected to be avoided by placement and location of transmission line facilities and roads outside of wetlands and streams. Less than 0.1 acre of wetlands and streams would be affected by new or upgraded road construction.

Movement Areas

Potential white-tailed deer movement corridors in the Crazy PSU may be affected where the Alternative B transmission line traversed or crossed the Howard, Libby, and Ramsey creek drainages. Alternative B could also interfere with deer movement in the Crazy PSU where it followed the ridge between Midas Creek and Howard Creek. Deer could be discouraged from using these areas during transmission line construction due to increased noise and the presence of humans and machinery, but these effects would be short-term, and would be minimized through construction timing restrictions. The width of clearing area would not likely be great enough to affect deer movement in these areas after the Construction Phase because sufficient cover would be present. Individual animals may have to adjust their localized movement patterns in the short term, but no barriers to movement would likely be created by Alternative B.

Impacts on White-tailed Deer on State and Private Lands

Alternative B would affect about 149 acres of white-tailed deer winter range on all lands in the analysis area, including 133 acres of private land, primarily in the Miller Creek drainage. Direct impacts on winter range would include a reduction in thermal and hiding cover and, once the transmission line corridor was revegetated, an increase in forage habitat. The risk of replacement of native forage species with unpalatable introduced species on private land would be similar to those described above for National Forest Systems lands, except that new roads on private land would not be reseeded, potentially increasing the spread of noxious weeds and reducing available forage.

Alternative B would increase road densities on state and private lands. Roads opened or constructed for transmission line access on private land would be gated after transmission line construction, and could result in increased white-tailed deer mortality if hunting access were allowed. Short-term habitat displacement could occur in the analysis area during transmission line construction as a result of increased road use during construction and helicopter use during line stringing. Helicopter use could contribute to short-term displacement of individual white-tailed deer from the transmission line corridor. Helicopter use for line stringing would occur during a relatively short period (about 10 days). Except for annual inspection and infrequent maintenance operations, helicopter use and other construction activities would cease after transmission line construction until decommissioning. Helicopter use and other activities could result in short-term disturbance of white-tailed deer during line decommissioning. Short-term disturbance impacts in white-tailed deer winter range from transmission line construction would be minimized by restricting construction during the winter.

Because white-tailed deer habitat on State and private lands including the Sedlak Park Substation and loop line, is generally degraded due to high road densities and logging in the past 20 to 30 years, and because of the short-term nature of human-caused disturbance, overall, white-tailed deer on private and State land would not likely be affected by Alternative B.

Private and State land in the eastern segment of the Alternative B transmission line alignment would occur within the wildlife approach area in the Fisher River valley. The proximity of this alignment to US 2 would result in a widening of disturbed area and may potentially discourage white-tailed deer movement within the approach area by decreasing cover. Transmission line construction activities could cause white-tailed deer to change their traditional movement patterns within this approach area, but these effects would be short-term because human-caused disturbance directly related to the project would cease when the transmission line construction was completed. Once revegetated, cleared areas could provide additional forage habitat. Some shrub and tree cover would be maintained in the transmission line right-of-way because only the largest trees would be removed, and would continue to provide cover. Because most of the habitat in the approach area, including in the Sedlak Park Substation and loop line footprint, potentially affected by Alternative B is degraded due to high road densities and logging in the past 20 to 30 years, and because of the short-term nature of human-caused disturbance, it is not likely that white-tailed deer movement within the approach area would be greatly affected by Alternative B.

Alternative C-R – Modified North Miller Creek Transmission Line Alternative

The effect on forage openings and movement areas of Alternative C-R would be the same as Alternative B. Two acres of wetlands would be within the clearing area. Other effects on key habitat features would be the same as Alternative B.

Cover/Forage

Impacts of Alternative C-R on cover relative to forage habitat in both summer range and MAs 10 and 11, percent thermal cover in MAs 10 and 11, and percent cover in MAs 15, 16, and 17 in the Crazy PSU would be the same as Alternative B (Table 203).

The effects of Alternative C-R on the risk of replacement of native forage species with unpalatable introduced species would be less than those described for Alternative B. The agencies' noxious weed mitigation measures described for Alternative 3 would be implemented in the agencies' transmission line alternatives. To the extent possible, MMC would survey all proposed ground disturbance areas for noxious weeds before initiating disturbance. Where noxious weeds were found, MMC would treat infestation the season before the activity was planned. For example, if timber clearing were planned to be in the spring or early summer, the survey and control would be implemented the previous fall. Areas surveyed would include all areas designated for timber removal. MMC would describe in final design plans the extent of which surveys and pretreatment would not be feasible. The proposed survey and treatment approach would be a part of the final Weed Control Plan, to be reviewed and approved by the lead agencies. Helicopter use for vegetation clearing in some areas would minimize the potential for exotic species introduction associated with road construction or improvement and the extent of vegetation clearing would be greater. The agencies' modifications to MMC's proposed weed control plan for Alternative B would more effectively control the spread of weeds, minimizing the replacement of forage species.

MMC would submit a final Vegetation Removal and Disposition Plan for lead agencies' approval (see section 2.5.2.5.2, *Vegetation Removal and Disposition Plan* in Chapter 2). The plan would apply to all National Forest System lands covered by the Plan of Operations and all State and private lands covered by the transmission line certificate. It would not apply to private lands affected by the substation and loop line. One of the plan's goals would be to minimize vegetation clearing, particularly in riparian areas. The plan would identify areas where clearing would be avoided, such as deep valleys with high line clearance, and measures that would be implemented to minimize clearing.

Open Road Density

No areas of MA 12 would be reallocated to MA 23 because no MA 12 would occur in the 500-foot transmission line corridor. In Alternative C-R, during line construction and operations, ORD in the Crazy PSU would decrease to 4.93 mi/mi^2 in MA 12 and would decrease to 3.7 mi/mi^2 in MAs 15, 16, 17, and 18 (Table 204). In Alternative C-R, ORD in MA 12 and MAs 15, 16, 17, and 18 would continue to be worse than the KFP standard, but because ORD would decrease, a KFP amendment to increase ORD in MA 12 would not be necessary.

The status of new or opened roads associated with Alternative C-R would be the same as Alternative B, except that on National Forest System lands, the status of roads opened or constructed for transmission line access would be gated or barriered and placed in intermittent stored service after line installation was completed. Intermittent stored service roads would be closed to traffic and would be treated so they would cause little resource risk if maintenance were not performed on them during the operation period of the mine and prior to their future need. The service roads would not be used for routine maintenance of the transmission line, but could be used for emergency repairs, such as a damaged insulator. New transmission line roads on National Forest System lands would be decommissioned and revegetated after closure of the mine and removal of transmission line. Although new roads would not result in increased motorized access, they may improve access for hunters on foot.

Helicopter use could contribute to short-term displacement of individual white-tailed deer from the transmission line corridor. In Alternatives C-R, D-R, and E-R, two seasons of helicopter construction would occur and the total duration of helicopter use each season would be about 2 months because helicopters would be used for vegetation clearing and structure construction. The type and duration of impacts from helicopter use for line stringing would be the same as Alternative B (about 10 days). Except for annual inspection and infrequent maintenance operations, helicopter use and other construction activities would cease after transmission line construction until decommissioning. Helicopters use and other activities could result in short-term disturbance of white-tailed deer during line decommissioning. In Alternative C-R, all construction and decommissioning activities on National Forest System and State trust lands would occur between June 16 and October 14, eliminating construction disturbance during winter and spring. Construction timing restrictions would reduce displacement effects. Overall, effects of helicopter activity on white-tailed deer would be minimal because sufficient habitat would be available for any deer displaced due to short-term disturbance, and because construction timing restrictions would reduce the extent of potential displacement effects.

Impacts on White-tailed Deer on State and Private Lands

Alternative C-R would affect about 162 acres of the 21,885 total acres of white-tailed deer winter range on all lands in the analysis area, including 114 acres on state and private lands, primarily in the Miller Creek and Fisher River drainages (Table 203 and Figure 89). Direct impacts on winter range would include a reduction in thermal and hiding cover and, once the transmission line corridor was revegetated, an increase in forage habitat. The risk of replacement of native forage species with unpalatable introduced species on private land would be similar to those described above for National Forest Systems lands, except that new roads on private land would not be reseeded, potentially increasing the spread of noxious weeds and reducing available forage.

The effect of Alternative C-R on road densities on state and private lands would be the same as Alternative B. A relatively short segment of the Alternative C-R transmission line would cross the Fisher River valley in the wildlife approach area, potentially discouraging white-tailed deer movement in a localized area due to transmission line construction activities. These effects would be short-term because human-caused disturbance directly related to Alternative C-R would cease when the transmission line construction was completed. The segment of Alternative C-R that would parallel US 2 would be primarily on private land where habitat is degraded due to high road densities and logging in the past 20 to 30 years and would be located upslope and out of the Fisher River valley; therefore, Alternative C-R, including the Sedlak Park Substation and loop line, would not likely affect white-tailed deer movement in the approach area.

Alternative D-R – Miller Creek Transmission Line Alternative

The effect on forage openings of Alternative D-R would be the same as Alternative B. The effect on key habitat features would be the same as Alternative C-R. Potential white-tailed deer movement corridors in the Crazy PSU could be affected where the Alternative D-R transmission line traversed or crossed the Howard and Libby creek drainages. Other effects of Alternative D-R on white-tailed deer movement would be the same as Alternative B.

Cover/Forage

Impacts of Alternative D-R on cover relative to forage habitat in both summer range and MAs 10 and 11, percent thermal cover in MAs 10 and 11, and percent cover in MAs 15, 16, and 17 in the Crazy PSU would be the same as Alternatives B and C-R (Table 203). The effects of Alternative D-R on the quality of forage due to the introduction of unpalatable species are similar to those described for Alternative C-R, except that the risk of replacing forage species with introduced species would be greater due to a slightly longer line.

Open Road Density

Alternative D-R would include the reallocation of MA 12 in a 500-foot corridor along the transmission line to MA 23. Impacts on ORD in MAs 15, 16, 17, and 18 in the Crazy PSU would be the same in Alternative D-R as Alternative C-R, except that during Alternative D-R construction, ORD would decrease to 3.8 mi/mi^2 in MAs 15, 16, 17, and 18 (Table 204). In Alternative D-R, ORD in MA 12 would decrease to 4.08 mi/mi^2 during transmission line construction and operations (Table 204). In Alternative D-R, ORD in MA 12 and MAs 15, 16, 17, and 18 would continue to be worse than the KFP standard, but because ORD would decrease, a KFP amendment to increase ORD would not be necessary.

The status, use, and reclamation of new or opened roads associated with the transmission line would be the same as Alternative C-R. The effects of vegetation clearing, structure placement, and line stringing would be the same for Alternative D-R as Alternative C-R.

Impacts on White-tailed Deer on State and Private Lands

Impacts of Alternative D-R on white-tailed deer would be the same as Alternative C-R except that Alternative D-R would affect about 144 acres of the 21,885 total acres of white-tailed deer winter range on all lands in the analysis area, including 114 acres on state and private lands, primarily in the Fisher River drainage (Table 203 and Figure 89).

Alternative E-R – West Fisher Creek Transmission Line Alternative

The effect on forage openings of Alternative D-R would be the same as Alternative B. The effect on key habitat features would be the same as Alternative C-R.

Cover/Forage

Impacts of Alternative E-R on cover relative to forage habitat in both summer range and MAs 10 and 11, percent thermal cover in MAs 10 and 11, and percent cover in MAs 15, 16, and 17 in the Crazy PSU would be the same as Alternatives C-R and D-R (Table 203). The effects of Alternative E-R on the quality of forage due to the introduction of unpalatable species are similar to those described for Alternatives C-R and D-R, except that the risk of replacing forage species with introduced species would be greater due to a longer clearing area.

Open Road Density

Impacts on ORD in the Crazy PSU would be the same for Alternative E-R as Alternative D-R. The status, use, and reclamation of new or opened roads associated with the transmission line would be the same as Alternative C-R. The effects of vegetation clearing, structure placement, and line stringing would be the same for Alternative E-R as Alternative C-R.

Movement Areas

Potential white-tailed deer movement corridors in the Crazy PSU could be affected where the Alternative E-R transmission line traversed or crossed the Howard, and Libby creek drainages. Other effects of Alternative D-R on white-tailed deer movement would be the same as Alternative C-R.

Impacts on White-tailed Deer on State and Private Lands

Impacts on white-tailed deer winter range from Alternative E-R would affect the most white-tailed deer winter range (about 188 acres of the 21,885 acres of winter range in the analysis area) on all lands in the analysis area. About 153 acres of white-tailed deer winter range on state and private land would be affected by Alternative E-R, primarily in the Fisher River and West Fisher Creek drainages (Table 203 and Figure 89). Otherwise, impacts of Alternative E-R on elk would be the same as Alternative C-R, except that in Alternative E-R the effects of helicopter use and the risk of replacing forage species with introduced species would be more extensive due to a longer clearing area.

Combined Mine-Transmission Line Effects

Impacts on white-tailed deer habitat in the analysis area from combined mine-transmission line alternatives are described below and shown in Table 205.

Cover/Forage

The combined mine-transmission line alternatives would not change cover relative to forage habitat or the percent thermal cover in MAs 10 and 11. Alternative 2B would result in a 4 percent decrease in cover relative to forage habitat in summer range, while cover in summer range would fall by 3 percent in all other combined action alternatives. Alternatives 2B, 4C-R, 4D-R, and 4E-R would reduce cover in MAs 15, 16, and 17 by 3 percent, indicating that mine Alternatives 2 and 4 would have the greatest influence on cover in MAs 15, 16, and 17. Most areas disturbed as a result of the combined mine-transmission line alternatives would not be available as foraging habitat until after mine closure and reclamation. Some areas would be reclaimed during operations and would provide foraging habitat once vegetation was established. In the long term, after reclamation success criteria are achieved, areas disturbed by the combined mine-transmission line alternatives would provide forage for white-tailed deer, thereby moving toward KFP objectives for forage habitat. The proportion of thermal cover in MAs 10 and 11 would not change as a result of the combined mine-transmission line alternatives and would continue to be less than the desired minimum. Percent cover in MAs 15, 16, and 17 in the Crazy PSU would decrease by 1 to 3 percent in the combined mine-transmission line alternatives, but would continue to be greater than the 30 percent KFP guideline minimum.

Open Road Density

For all combined mine-transmission line alternatives, any MA 15, 16, 17, or 18 in the mine permit area or MA 12 in a 500-foot corridor of the transmission line centerline would be reallocated to MA 31 or MA 23, as appropriate. Road density calculations take into account MA reallocation.

Current ORD in MA 12 and MAs 15, 16, 17, and 18 in the Crazy PSU is higher than the standard (Table 206). In Alternatives 2B, 3C-R, and 4C-R, ORD in MA 12 would decrease to 4.93 mi/mi^2 during construction and operations. In Alternatives 3D-R, 3E-R, 4D-R, and 4E-R, ORD in MA 12 would decrease during construction and operations to 4.08 mi/mi^2. Alternative 2B would increase ORD in MAs 15, 16, 17, and 18 to 4.8 mi/mi^2 during construction and 4.5 mi/mi^2 during operations. In all combined agency mine-transmission line alternatives, ORD in MAs 15, 16, 17, and 18 would decrease during construction and operations to 3.8 mi/mi^2.

Alternative 2B would increase ORD in MAs 15, 16, 17, and 18 in the Crazy PSU, where standards are not currently met (Table 206), and would require a KFP amendment to increase road densities. Specifically, the KFP amendment for increases in ORD would apply to: MAs 16 and 17 in sections 14, 15, and 24 in T28N, R31W; sections 18 and 19 in T28N, R30W; MAs 15 and 16 in sections 7, 8, 17, and 18 in T27N, R30W; and sections 1, 2, and 12 in T27N, R31W.

In the agencies' combined mine-transmission line alternatives, ORD in MAs 15, 16, 17, and 18 would continue to be worse than the KFP standard, but because ORD would decrease, a KFP amendment to increase ORD would not be necessary. None of the combined mine-transmission line alternatives would increase ORD in MA 12 in the Crazy PSU, where road densities continue to exceed standards, and a KFP amendment to increase ORD in MA 12 would not be necessary.

In all combined mine-transmission line alternatives, the new road prism would remain during transmission line operations. In Alternative 2B, roads opened or constructed for transmission line access would be gated or barriered on National Forest System land after transmission line construction. In the agencies' alternatives, roads on National Forest System land would be placed into intermittent stored service after line installation was completed. Intermittent stored service roads would be closed to traffic and would be treated so they would cause little resource risk if maintenance were not performed on them during the operation period of the mine and prior to their future need. The service roads would not be used for routine maintenance of the transmission line, but could be used for emergency repairs, such as a damaged insulator. In all combined mine-transmission line alternatives, roads opened or constructed for transmission line access on private land would be gated after transmission line construction. In all combined mine-transmission line alternatives, new roads could improve access for hunters on foot. During the final Closure Phase following mine closure, the transmission line would be removed, roads reclaimed, trees along the line allowed to grow, and all disturbed areas revegetated. For agencies' alternatives, roads would be decommissioned at mine closure.

[2] Ops = during transmission line and mine operations.
[3] All MA 12 and MA 15, 16, 17, and 18 within a 500-foot corridor of the transmission line centerline would be reallocated to MA 23. All MA 15, 16, 17, and 18 in the mine alternative permit area would be reallocated to MA 31. MA reallocation was taken into account in road density calculations.
Source: GIS analysis by ERO Resources Corp. using KNF data.

In all combined mine-transmission line alternatives, road densities would likely improve through the grizzly bear land acquisition requirement, as described in sections 2.5.6, *Mitigation Plans*. Acquired parcels would be managed for grizzly bear use in perpetuity, and could improve road densities where roads could be closed. The agencies' land acquisition requirement would likely be more effective at reducing road densities than MMC's proposed land acquisition because more land would be protected.

In all combined mine-transmission line alternatives, widening, improvement, and yearlong access of the Bear Creek Road would lead to increased vehicle volumes and speed. and loss of the Little Cherry Loop Road beneath the impoundment percent (Table 172 in section 3.21, *Transportation*). The increase in traffic in the combined mine-transmission line alternatives would substantially increase the risk of increased deer mortality. MMC would provide transportation to employees using buses, vans, and pickup trucks, thereby limiting use of personal vehicles. MMC would report road-killed animals to the FWP as soon as road-killed animals were observed. The FWP would either remove road-killed animals or direct MMC how to dispose of them. In the agencies' combined mine-transmission line alternatives, MMC would remove big game animals killed by any vehicles daily from road rights-of-way within the permit area and along roadways used for access or hauling ore for the life of the mine and monitor the number of big game animals killed by vehicle collisions on these roads and report findings annually. When the mill ceased operations in the Closure Phase, mine traffic volume would be substantially less than shown in Table 172 in section 3.21, *Transportation*. Future traffic volume when all activities at the mine are completed in the Post-Closure Phase would be higher than in Alternative 1 because of reconstruction of Bear Creek Road and loss of the Little Cherry Loop Road beneath the impoundment. Mortality risk to white-tailed deer would decrease on the Bear Creek Road compared to operations, but the permanently improved road conditions (increased road width, improved sight distance, paving) and higher traffic speeds would result in a permanently higher deer risk mortality compared to pre-mine conditions. At mine closure, all new roads (except the Bear Creek access road) constructed for the project would be reclaimed, which would include grading to match the adjacent topography and obliterating the road prism. After reclamation success criteria are achieved, areas disturbed by road use would provide forage for white-tailed deer.

For all action alternatives, helicopter and other transmission line construction activities could result in short-term displacement of white-tailed deer from the transmission line corridor and surrounding habitat. Disturbance from helicopter use and other transmission line construction activities are described for Alternatives B and C-R above.

Forage Openings

In all combined mine-transmission line action alternatives, one opening greater than 20 acres would be created in MA 11 along the Bear Creek Road near US 2. Effects on white-tailed deer of this new opening would likely be minimal because no point would be more than 600 feet to cover, and due to its proximity to US 2 and private property. The loss in forage capacity may impact individual white-tailed deer in the short term, until disturbed areas were successfully revegetated.

Movement Areas

Alternatives 2B, 3D-R, and 3E-R would affect the fewest number of potential white-tailed deer movement areas. The agencies' alternatives could interfere with white-tailed deer movement where it followed the east-facing ridge north of the Sedlak Park Substation. Alternative 2B would be located at a lower elevation in the Fisher River valley and would not impact this area, but could affect white-tailed deer movement in the Ramsey Creek drainage. Alternatives 2B, 3C-R, and 4C-R could interfere with white-tailed deer movement where the transmission lines followed the ridge between Midas Creek and Howard Creek. Potential white-tailed deer movement along the ridge between Miller Creek and Howard Creek could be affected by Alternatives 4C-R and 4D-R. White-tailed deer could be discouraged from using these areas during transmission line construction due to increased noise from helicopters and machinery and the presence of humans, but these effects would be short-term. The width of clearing area would not likely be great enough to affect white-tailed deer movement in this area after the Construction Phase because sufficient cover would be present.

Key Habitat Features

Alternatives 2B, 4C-R, 4D-R, and 4E-R would have the greatest impacts on wetland habitat potentially providing water and high-quality forage for white-tailed deer in the Crazy PSU. Impacts on wetland habitat would range from 31 acres for Alternatives 3C-R, 3D-R, and 3E-R to 45 acres for Alternative 2B.

In Alternative 2B, MMC would implement its proposed Wetland Mitigation Plan. The feasibility of MMC's proposed Wetland Mitigation Plan to replace the lost functions of all potentially affected wetlands is uncertain. MMC's plan is conceptual and would be refined during the 404 permitting process. MMC did not update its mitigation plan for Alternative 2 to reflect new wetland and stream mitigation regulations and procedures. Impacts on wetlands from the agencies' combined mine-transmission line alternatives would be mitigated through implementation of the agencies' Wetland Mitigation Plan, which would have a greater likelihood of replacing lost functions than the Alternative 2 Wetland Mitigation Plan. Section 3.23, *Wetlands and other Waters of the U.S.*, discusses proposed wetland mitigation in more detail.

For the transmission lines, direct effects to wetlands are expected to be mostly avoided by placement and location of transmission line facilities and roads outside of wetlands and streams.

Mine Water Management

In Alternative 2B, MMC would store mine, adit, or tailings water at the Ramsey Plant Site, a surge pond at the LAD Areas, and the tailings impoundment. The metals in the tailings water would be similar to what is found at the Troy Mine decant ponds (see Table 120 in the *Water Quality* section), where adverse effects on wildlife have not been observed (USDA Forest Service and DEQ 2012). Concentrations of metals in mine and adit water, which would be stored in mine/yard pond at the Ramsey Plant Site and in a surge pond at the LAD Areas, would be lower than tailings water (see Table 120 in the *Water Quality* section). The Ramsey Plant Site would be fenced, restricting deer access.

Water management in the agencies' combined mine-transmission line alternatives would reduce the risk to wildlife from contaminant uptake from storage of mine, adit, and tailings water. All mine and adit water would be treated and discharged at the Libby Adit Water Treatment Plant and not stored in ponds. The LAD Areas would not be used and the surge ponds would not pose a risk to white-tailed deer. Tailings water quality would have lower metal concentrations than in Alternative 2; the factors leading to lower metal concentrations in tailings water quality in Alternatives 3 and 4 are discussed in section 3.13, *Water Quality*, p. 674.

White-tailed Deer Winter Range on All Lands

Impacts on white-tailed deer winter range from the combined action alternatives on all lands in the analysis area, including private and State lands, would range between 144 and 188 acres of the 21,885 total acres in the analysis area. Alternatives 3E-R and 4E-R would have the greatest impacts on white-tailed deer winter range, while Alternatives 3D-R and 4D-R would have the fewest impacts on winter range. In all combined action alternatives, direct impacts on winter range would include a reduction in thermal and hiding cover and, once the transmission line corridor was revegetated, an increase in forage habitat. Impacts on white-tailed deer winter range would likely be minor in all combined action alternatives, relative to the total amount of winter range habitat available in the analysis area. Impacts on white-tailed deer winter range would be eliminated through application of construction timing restrictions in white-tailed deer winter range. All combined action alternatives would result in increased road densities on state and private lands. Roads opened or constructed for transmission line access on private land would be gated after transmission line construction, and could result in increased white-tailed deer mortality if hunting access were allowed. State and private lands, including in the Sedlak Park Substation and loop line footprint, currently have high road densities and have been logged in the past 20 to 30 years and overall white-tailed deer populations would not likely be affected. Short-term habitat displacement could occur in the analysis area during transmission line construction as a result of helicopter use.

Wildlife Approach Area

The eastern segment of the Alternative 2B transmission line corridor would occur within the wildlife approach area in the Fisher River valley and relatively small segments of the transmission line corridors for the agencies' combined mine-transmission line alternatives would cross the Fisher River valley in the wildlife approach area, potentially discouraging elk movement in a localized area due to transmission line construction activities. The portions of the agencies' combined alternatives that would parallel US 2 would be primarily on private land and would be located upslope and out of the Fisher River valley. The proximity of the Alternative 2B alignment to US 2 would result in a widening of disturbed area and could potentially discourage white-tailed deer movement within the approach area by decreasing cover. Alternative 2B transmission line construction activities could cause white-tailed deer to change their traditional movement patterns within this approach area, but these effects would be short-term because human-caused disturbance directly related to the project would cease when the transmission line construction was completed. Effects of the combined mine-transmission line alternatives, including construction of the Sedlak Park Substation and loop line, on white-tailed deer movement within the approach area would likely be minimal because: most of the habitat in the approach area in the study area is degraded due to high road densities and logging in the past 20 to 30 years; human-caused disturbance would be short-term; and for the agencies' combined mine-transmission line alternatives, relatively small segments of the transmission line corridors would cross the Fisher River valley.

Cumulative Effects

Past Actions and the Existing Condition

Past actions, including detailed descriptions of previous vegetation and road management activities, are described in section 3.2, *Past and Current Actions*, shown on Figure 50, and listed in Appendix E.

Forest management practices and other human activities (*e.g.,* hunting, wood consumption, and motorized recreation) have had influential cumulative impacts on white-tailed deer and other big-game security, as well as measurable fluctuations in cover to forage ratios. Harvest has occurred in the analysis area since the 1950s and resulting in a diversity of age classes and successional stages which provide forage and cover for white-tailed deer and other big game species; however, most past harvest areas have recovered to the point they are no longer considered openings and contribute to the high cover to forage ratio in the Crazy PSU. Historically, wildfire would create a mosaic of successional stages and result in vegetative diversity in this area. Since the mid-1990s, there has also been a greater use of intermediate harvest methods, which results in both hiding cover and foraging opportunities occurring in close proximity. Although more recent logging and prescribed burning has helped cycle forest cover through successional communities, fire suppression and past timber management has resulted in a trend toward homogenous stand composition and structure consisting of high density stands of shade-tolerant species (see section 3.22, *Vegetation*) that reduce the presence and productivity of understory forage species. The current conditions of various white-tailed deer habitat components are displayed in Table 204 and Table 205.

New roads decrease white-tailed deer and other big-game security (increasing vulnerability or risk of mortality), decrease habitat availability via temporary displacement, and can increase stress levels of resident species. KFP standards for open and total road densities have been and will continue to be an important tool to mitigate the associated cumulative impacts to white-tailed deer and other big-game. Activities affecting white-tailed deer habitat have changed in recent years, with a trend toward reduced motorized access as a result of decisions intended to facilitate grizzly bear recovery. This in turn has benefited white-tailed deer with the resulting decrease in ORD.

Development of private lands within the analysis area, including commercial timber harvest, land clearing, home construction, and road construction has contributed to increased disturbance of white-tailed deer and a loss or reduction in quality of foraging and winter habitat, and is expected to continue.

Areas previously impacted by special use permits such as mineral material sites (pits quarries, borrow, roadsides), water developments, utility corridors, private land access routes, and outfitter/guide trails/camps, would continue to be used. The ground disturbance on resources such as white-tailed deer winter range and cover is described previously for the affected environment and would have no additional impacts. Other public uses such as wildlife viewing, berry picking, firewood gathering, camping, snowmobiling, etc. have negligible impacts on white-tailed deer given their limited scope (time and space). Infra-structure, such as roads and campgrounds, that facilitate these activities have already been accounted in the description of the affected environment.

Effects of Current and Reasonably Foreseeable Actions

Reasonably foreseeable actions are described in section 3.3, *Reasonably Foreseeable Future Action or Conditions*. Current actions are described in section 3.2, *Past and Current Actions* and shown on Figure 50. Reasonably foreseeable actions located in the Crazy PSU include the Libby Creek Venture Drilling Plan and the Poker Hill Rock Quarry. Surface impacts from reasonably foreseeable actions would be minimal, and would not result in any measurable changes in cover or forage habitat.

New roads and roads closed for mitigation associated with reasonably foreseeable actions such as the Rock Creek Project and the Wayup Mine/Fourth of July Road Access Project, will contribute to cumulative effects on ORD in the Crazy PSU (Table 207). Reasonably foreseeable actions would increase ORD in MAs 15, 16, 17, and 18 by 0.1 mi/mi^2 to 4.4 mi/mi^2 and would reduce ORD in MA 12 to 4.87 mi/mi^2.

The Coyote Improvement vegetation management project is in the planning stages and would take place within the Crazy PSU. The project would harvest 240 acres to increase stand resiliency to mountain pine beetles. This project would contribute to open canopy habitat/openings within the analysis area. This habitat component is generally lacking on the landscape and Coyote Improvement project would contribute toward improving its availability within these planning subunits. The transmission line alternatives in Montanore would contribute openings as well, although they are expected to be maintained longer before natural succession is allowed to occur compared to Coyote Improvement.

Silverbutte Bugs timber sale is in the Silverfish PSU and would be a small project like Coyote. Similar to the timber sales mentioned above, it would contribute some openings/open-canopied habitat within this PSU. If Silverbutte Bugs mainly treats stands already impacted by insects/disease, those stands may already be in an open-canopied condition.

Flower Creek timber sale is in the Treasure PSU and only has minimal overlap with the project with a small amount of the access road for Montanore located within this PSU. Flower Creek timber sale, like the timber sales mentioned above, would contribute openings or open-canopied habitat as well. Approximately 900 acres are proposed for treatment. Due to the minimal overlap, cumulative effects would be minimal.

Road management actions such as road maintenance and administrative use associated with permit administration, data collection and monitoring of National Forest System lands are not likely to affect white-tailed deer habitat because they generally do not result in vegetation removal. White-tailed deer and other large ungulates will typically simply avoid the disturbance area until human activities terminate, which usually comprises of a few hours. Although water restoration projects may temporarily displace white-tailed deer and other wildlife from a localized area, they typically benefit wildlife in the long-term by providing pulses of foraging when seeded or by stabilizing soils where certain habitat components can remain available.

With population growth and development, it is reasonable to assume that some corresponding increase in human use of National Forest System lands is likely to occur. Recreational activities such as sightseeing, hiking, cross-country skiing, camping, snowmobiling, fishing, and firewood cutting are ongoing and expected to increase over the next 10 years. This increase is likely to be gradual and incremental and tend to be focused on areas along or near roads open to motorized traffic. White-tailed deer may, over time, experience more frequent disruption of their daily activities if they are in proximity to roads.

Table 207. Cumulative Effects to White-tailed Deer Habitat Components on National Forest System Land in the Crazy PSU by Combined Mine-Transmission Line Alternative.

Measurement Criteria	[1] Existing Condition	[1] No Mine1[1]	[2] MMC's Proposed Mine		[3] Agency Mitigated Poorman Impoundment 1Alternative						[4] Agency Mitigated Little Cherry Creek Impoundment Alternative

ORD in MAs 15, 16, 17, and 18 (mi/mi^2) Standard is <3.0[4]	4.3	4.4	4.6	4.2	3.8	3.8	3.8	3.8	3.8	3.8	3.8	3.8	3.8	3.8	3.8	3.8

[1] Effects shown include effects of the Wayup Mine/Fourth of July Road Access Project, Plum Creek activities, the Rock Creek Project, and the Miller-West Fisher Vegetation Management Project. Alternative 1 (No Transmission Line) would not contribute to cumulative effects on ORD.
[2] Const = during mine construction.
[3] Ops = during transmission line and mine operations.
[4] All MA 12 and MA 15, 16, 17, and 18 within a 500-foot corridor of the transmission line centerline would be reallocated to MA 23. All MA 15, 16, 17, and 18 in the mine alternative permit area would be reallocated to MA 31. MA reallocation was taken into account in road density calculations.
Source: GIS analysis by ERO Resources Corp. using KNF data.

Activities on private land, such as timber harvest, land clearing, home construction, road construction, and livestock grazing, are likely to continue on private lands within the Crazy PSU and would likely slightly impact cover and ORD. Potential effects depend on the magnitude, type and location of developments and include the loss of habitat and localized disturbance on white-tailed deer and other big game species. Private lands occupy 10 percent of the Crazy PSU. Because the proportion of white-tailed deer habitat in the Crazy PSU on private lands is small, development of private lands is expected to have minor cumulative impacts on white-tailed deer and other big game species within the analysis area over the next 10 years.

No Action Alternative

The Montanore Project No Action alternatives (Alternative 1 and Alternative A) would not contribute to cumulative impacts on white-tailed deer.

Combined Mine-Transmission Line Action Alternatives

Open Road Density

Alternatives 2B, 3C-R, and 4C-R, along with reasonably foreseeable actions, would result in an ORD decrease in MA 12 in the Crazy PSU to 4.93 mi/mi^2 during construction and operations, which is less than existing ORD. Cumulative ORD in MA 12 in the Crazy PSU in Alternatives 3D-R, 3E-R, 4D-R, and 4E-R would be 4.08 mi/mi^2 during construction and operations. In all alternatives, cumulative ORD in MA 12 in the Crazy PSU would be less than existing conditions due to road access changes associated with the Montanore mine-transmission line alternatives and other reasonably foreseeable actions.

In MAs 15, 16, 17, and 18 in the Crazy PSU, cumulative ORD would increase to 4.6 mi/mi^2 during construction in Alternative 2B, but would decrease to 4.2 mi/mi^2 during operations. The agencies' combined mine-transmission line alternatives, in combination with other reasonably foreseeable activities, would reduce ORD in MAs 15, 16, 17, and 18 in the Crazy PSU to 3.8 mi/mi^2 during construction and operations due to road access changes associated with the Montanore mine-transmission line alternatives and other reasonably foreseeable actions. In all combined mine-transmission line action alternatives, cumulative ORD would remain greater than KNF standards in MA 12 and MAs 15, 16, 17, and 18.

Forage Openings

Other reasonably foreseeable actions would not occur in MAs 10 and 11 and would not contribute to cumulative effects on forage openings in these areas. In all combined mine-transmission line action alternatives, one opening greater than 20 acres would be created in MA 11 along the Bear Creek Road near US 2. Effects on white-tailed deer of this new opening would likely be minimal because no point would be more than 600 feet to cover, and due to its proximity to US 2 and private property. The loss in forage capacity may impact individual white-tailed deer in the short term, until disturbed areas were successfully revegetated.

Key Habitat Features

All action alternatives would result in the disturbance of wetlands providing potential water and high-quality forage habitat for white-tailed deer in the Crazy PSU. Impacts on wetlands would be mitigated through implementation of the MMC's or the agencies' Wetland Mitigation Plans. Other reasonably foreseeable actions would contribute to losses of wetland habitat. Impacts on wetlands from reasonably foreseeable actions would require mitigation under the Clean Water Act.

Movement Areas

The mine action alternatives could interfere with white-tailed deer movement in the Little Cherry, Poorman, and Libby creek corridors. The transmission line alternatives could affect white-tailed deer movement where the lines traversed or crossed the Howard and Libby creek drainages. Alternative B could also disrupt movement in the Ramsey Creek corridor. Disturbance-related impacts from transmission line construction would be short-term and the width of clearing area would not likely be great enough to affect deer movement after the Construction Phase. Other reasonably foreseeable actions could impede deer movement in specific areas due to increased road use and noise disturbance, but KNF riparian standards would minimize activities in riparian areas. While some cumulative effects to white-tailed deer movement could occur, they would likely be minimal.

White-tailed Deer Winter Range on All Lands

All combined mine-transmission line action alternatives, in combination with other reasonably foreseeable actions, would result in cumulative impacts on white-tailed deer winter range on all lands in the analysis area, resulting in a reduction of thermal and hiding cover and, once disturbed areas were revegetated, an increase in forage habitat. Cumulative impacts of all combined mine-transmission line action alternatives would likely be minor because application of construction timing restrictions in winter range would minimize impacts. The combined mine-transmission line action alternatives, in combination with Plum Creek activities, could result in cumulative disturbance to white-tailed deer on private lands in the analysis area, and could displace white-tailed deer away from areas of disturbance. Because most of the habitat on private land in the study area is degraded due to high road densities and logging in the past 20 to 30 years and because human-caused disturbance would be short-term, effects of the combined mine-transmission line alternatives on white-tailed deer winter range would likely be minimal.

Wildlife Approach Area

The combined mine-transmission line action alternatives, in combination with Plum Creek activities, could result in cumulative disruption of white-tailed deer movement in the wildlife approach area. Because most of the habitat on private land in the wildlife approach area in the study area is degraded due to high road densities and logging in the past 20 to 30 years and because human-caused disturbance would be short-term, effects of the combined mine-transmission line alternatives on white-tailed deer movement within the approach area would likely be minimal.

Cumulative Effects of Plan Amendments for Open Road Density (MA 12)

Alternative 2B would increase ORD in MAs 15, 16, 17, and 18 in the Crazy PSU, where standards are not currently met (Table 206), and would require a KFP amendment to increase road densities. Specifically, the KFP amendment for increases in ORD would apply to: MAs 16 and 17 in sections 14, 15, and 24 in T28N, R31W; sections 18 and 19 in T28N, R30W; MAs 15 and 16 in sections 7, 8, 17, and 18 in T27N, R30W; and sections 1, 2, and 12 in T27N, R31W.

Johnson (2006) analyzed the cumulative effects of the KFP amendment for changing the ORD requirements. This analysis looked at post-project changes in ORD, both increases and decreases, and calculated a cumulative change to ORD in MA 12. Since 2006, only six projects have received a project specific amendment for ORD in MA 12, which now total 46 for the KNF (USDA Forest Service 2013b). Of these, four of the projects would have high ORD levels during implementation but would return to the existing condition post-project. One project would improve upon the existing ORD level post-project and ORD would become better than the MA standard.

As described under the Affected Environment section, the white-tailed deer population appears to be increasing which may be due to increased road restrictions and decommission in the past 20 years (USDA Forest Service 2008c). The cumulative effects of past and present land use patterns as well as random natural events have been taken into consideration in this analysis.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Mineral Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8. In the proposed action, MMC did not propose to implement feasible measures to minimize effects on the white-tailed deer or all practicable measures to maintain and protect wildlife habitat. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would comply with 36 CFR 228.8. The agencies' alternatives would incorporate additional feasible and practicable measures to minimize adverse environmental impacts on wildlife habitat that benefit white-tailed deer, including yearlong access changes through the installation of barriers or gates in several roads to reduce ROD and mitigate for impacts to big game (Table 28 and Table 29 and Figure 35), daily removal of any big game animals killed by vehicles from road rights-of-way within the permit area and along roadways used for access or hauling ore for the life of the mine, and monitoring and annual reporting of the number of big game animals killed by vehicle collisions on these roads. In the agencies' alternatives, Highway safety signs such as "Caution – Truck Traffic" would help slow public traffic speeds in anticipation of meeting oncoming trucks, and staging shipments of supplies in a general location prior to delivery to the mine site would reduce traffic and deer mortality risk.

National Forest Management Act/Kootenai Forest Plan

1. Forestwide Management Direction – KFP II-1 #3, #7, II-2 #12, #17, II-7, 22, 23

#3 – *Maintain a balance of open and closed road… (to) insure big-game habitat security…:* In all combined mine-transmission line alternatives, although during transmission line construction some restricted, impassable/barriered, and temporary roads would be opened and some new access roads would be needed, road access changes to mitigate for impacts on grizzly bear would be implemented. The agencies' alternatives would also include additional access changes in numerous roads to mitigate for the loss of big game security (Figure 35 and Table 28 and Table 29).

#7 – *Maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species:* Cover to forage ratios in the Silverfish PSU indicate that the proportion of forage habitat is well below recommended levels. Current populations of white-tailed deer would likely be maintained in all mine-transmission line action alternatives because changes to cover to forage ratios would be 4 percent or less, and because while cover would decrease relative to forage, the Crazy PSU provides an abundance of cover. The combined mine-transmission line alternatives would not change cover relative to forage habitat or the percent thermal cover in MAs 10 and 11. In the long term, after reclamation success criteria are achieved, areas disturbed by the combined mine-transmission line alternatives would provide forage for white-tailed deer, thereby moving toward KFP objectives for forage habitat.

#12 – *Maintain big-game habitat to support the recreational hunting demand for resident big-game species:* Except for thermal cover in MAs 10 and 11, levels of cover in the Crazy PSU would be maintained above recommended guidelines in all combined mine-transmission line alternatives, and would provide for habitat conditions maintaining the existing populations of elk for local hunting demand. Overall, road densities would likely continue to improve through land acquisition associated with grizzly bear mitigation.

#17 – *Use prescribed fire to simulate natural ecological processes… create habitat diversity for wildlife…* None of the alternatives would include prescribed burns.

p.II-7 –Habitat maintenance to support huntable populations of all other big game species as well as viable population levels of all endemic vertebrate species of wildlife: Based on FWP data, the KNF's 2007 Monitoring and Evaluation Report (USDA Forest Service 2008c) concluded that white-tailed deer are the most abundant and widespread big game animal in the KNF, and that the white-tailed deer population in the KNF is steadily increasing. Except for thermal cover in MAs 10 and 11, in all combined mine-transmission line alternatives, levels of cover in the Crazy PSU would be maintained above recommended guidelines and would provide for habitat conditions maintaining the existing populations of elk for local hunting demand. Overall, road densities would likely continue to improve through land acquisition associated with grizzly bear mitigation.

p.II-22, 23 – Maintenance of viable populations of existing native and desirable non-native vertebrate species, as monitored through indicator species, attained through the maintenance of a diversity of plant communities and habitats: See #7 above for habitat diversity. White-tailed deer are monitored as an indicator species for general forest habitat. Their occurrence and estimation of population is monitored through District observations, FWP surveys, and KNF Monitoring and Evaluation Reports.

2. Applicable Management Area Direction (MAs 10, 11, 12, 15, 17, and 18) –KFP III-39, 44/45, 48/49/51, 65, and 75.

Objectives of the proposed mine-transmission line action alternatives are to facilitate mine development. Mine-transmission line action alternatives would include the re-allocation of MAs 15, 16, 17, and 18 in the mine permit areas and MA 12 lands in a 500-foot corridor along the transmission line to MA23.

MA 10 (Big Game Winter Range) – Maintain or enhance the habitat effectiveness for winter use by big game species through cover/forage ratios, prescribed fire, and maintenance of wildlife movement patterns: None of the combined mine-transmission line alternatives would affect cover to forage ratios or percent thermal cover in MA 10.

MA 11 (Timber/Big Game Winter Range) – Maintain or enhance the winter range habitat effectiveness for big game species (while also achieving timber and visual goals) through prescribed fire, maintenance of wildlife movement patterns/corridors, management of key habitat components as riparian areas, and utilizing harvest to achieve desired cover/forage ratios, a variety of seral stages, and maximization of edge effect in units generally not exceeding 40 acres: See description for MA 10 above.

MA 12 (Timber/Big Game Summer Range) – Maintain or enhance non-winter big game habitat (while also achieving timber goals) through habitat diversity, maximization of edge effect in units generally not exceeding 40 acres, maintaining hiding cover between openings, management of key habitat components as riparian areas, managing open roads to no more than ¾ miles per square mile: Alternatives 3D-R, 3E-R, 4D-R, and 4E-R would include the reallocation of MA 12 in a 500-foot corridor along the transmission line to MA 23. The amendment would be for the duration of the proposed Montanore Project. ORD in MA 12 would improve in all combined mine-transmission line alternatives.

MA 15 (Timber Production) - Produce timber using various standard silvicultural practices while providing for other resource values such as wildlife, including big game, through maintenance of habitat effectiveness and security by limiting ORD to a maximum of 3 miles per square mile and management of key habitat components, such as riparian areas: For all combined mine-transmission line alternatives, any MA 15, 16, 17, or 18 in the mine permit area would be reallocated to MA 31. The agencies' combined mine-transmission line alternatives would improve ORD in MAs 15, 16, 17, and 18. In MAs 15, 16, 17, and 18 in the Crazy PSU, cumulative ORD would increase to 4.5 mi/mi^2 during construction in Alternative 2B, but would decrease to 4.2 mi/mi^2 during operations. Alternative 2B would require a KFP amendment to increase road densities in MAs 15, 16, 17, and 18. Specifically, the KFP amendment for increases in ORD would apply to: MAs 16 and 17 in sections 14, 15, and 24 in T28N, R31W; sections 18 and 19 in T28N, R30W; MAs 15 and 16 in sections 7, 8, 17, and 18 in T27N, R30W; and sections 1, 2, and 12 in T27N, R31W. All key habitat components have been identified and maintained under all alternatives.

MA 16 (Timber with Viewing) - Produce timber while providing for a pleasing view. Manage wildlife habitat to provide for viable populations of existing native species, including big game, through maintenance of habitat effectiveness and security by limiting ORD to a maximum of 3 miles per square mile and management of key habitat components, such as riparian areas: See MA 15 above.

MA 17 (Viewing with Timber) - Provide landscapes that are pleasing to the viewer, while producing a level of timber production that is compatible with visual resource protection. Manage wildlife habitat to provide for viable populations of existing native wildlife species, including big game, through maintenance of habitat effectiveness and security by limiting ORD to a maximum of 3 miles per square mile and management of key habitat components, such as riparian areas: See MA 15 above.

MA 18 (Regeneration Problem Areas; Steep Slopes) – Maintain existing vegetation (future timber production) and viable populations of existing native wildlife species, including big game, through maintenance of habitat effectiveness and security by limiting ORD to a maximum of 3 miles per square mile and management of key habitat components, such as riparian areas: See MA 15 above.

Forest Service Management Indicator Species Statement of Findings

KFP direction is to "maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species,… in sufficient quality and quantity to maintain viable populations" (KFP Vol. 1, II-1 #7). ***Based on the white-tailed deer analysis and the KNF Conservation Plan (Johnson 2004a), all combined mine-transmission line alternatives would provide general forest species habitat with sufficient quality and quantity of the diverse age***

classes of vegetation needed for viable populations. In all combined mine-transmission line alternatives, sufficient general forest habitat would be available; the populations of species using that habitat should remain viable.

The mine-transmission line action alternatives would decrease cover to forage ratios in summer range, decrease percent cover in MAs 15, 16, 17, and 18, and increase displacement. Alternative 2B would increase ORD in MAs 15, 16, 17, and 18 where ORD is currently worse than the standard. In all combined mine-transmission line alternatives, road densities would likely improve through the grizzly bear land acquisition requirement, as described in sections 2.5.6, *Mitigation Plans*. Acquired parcels would be managed for grizzly bear use in perpetuity, and could improve road densities where roads could be closed. The agencies' land acquisition requirement would likely be more effective at reducing road densities than MMC's proposed land acquisition because more land would be protected. Based on the white-tailed deer analysis of general forest habitat indicators and the KNF Conservation Plan (Johnson 2004a), sufficient quality and quantity of diverse habitat types and age classes of vegetation are available and would continue to be available to support white-tailed deer populations in the Silverfish PSU.

State Requirements

Alternatives 3 and 4 would comply with the MMRA regarding disturbed lands being reclaimed to a post-mining land use with stability and utility comparable to that of the pre-mining landscape. Draft findings regarding compliance with MFSA requirements are discussed in the Summary, beginning on p. S-53. White-tailed deer and other ungulate populations are managed by FWP. Proposed actions would not prevent the state from continuing to manage these species as harvestable populations.

3.25.3.4 Mountain Goat

3.25.3.4.1 Analysis Area and Methods

The mountain goat is the KNF MIS for alpine habitat. Mountain goat ecology, biology, habitat use, status, and conservation are described and summarized in Joslin (1980) and Brandborg (1955). That information is incorporated by reference. Mountain goat occurrence data come from District wildlife observation records, Forest historical data (NRIS Wildlife) and other agencies (FWP).

Habitat mapping for mountain goat is derived from Joslin (1980), and is categorized according to seasonal use (winter and summer, range). Five habitat categories are defined in Joslin (1980) and mapped by Brown (2006). Because winter range is limited and critical for the annual overwinter survival and productivity of mountain goats, any impact on winter range, whether categorized as confirmed, likely, or possible winter range, was considered as an impact on winter range. Likewise, areas used by goats to transition between summer and winter range (transitional summer range) and areas regularly used by mountain goats during summer (summer range) were combined into a single summer range because mountain goats may be found in any of these areas during warm seasons.

Mountain goats have been shown to be sensitive to human disturbances such as helicopter use, blasting, and road building (Joslin 1980; Côte 1996; Côte *et al.* 2013, Goldstein *et al.* 2005, Wilson 2005). Increased disturbance may result in displacement from suitable habitat. Mountain goats may also remain in proximity of the disturbance, potentially suffering increased stress levels that could result in a decline in reproductive rates (Ibid.). Mountain goats have been found to be moderately to strongly disturbed by helicopter flights less than 500 meters horizontal distance (Côte *et al.* 2013) Disturbance responses decrease with horizontal distance up to 1,500 meters where goats have little to no response to helicopter flights (Ibid.). Côte *et al.* (2013) and Cadsand (2012) suggest a minimum separation distance of 1,500 meters between helicopter flights and goat range, thus, the influence zones (1 mile or about 1,600 meters) suggested for grizzly bear in the Cumulative Effects Model (USDA Forest Service *et al.* 1988; USDA Forest Service *et al.* 1990) were used to estimate the displacement effects of disturbances associated with mine and transmission line construction and operations on mountain goats. Disturbance effects were calculated by applying the following buffers: 0.25 mile on each side of open roads (including seasonally open roads that are open during bear year from April 1 to Nov. 30) and 1 mile on each side of helicopter construction disturbance. In all transmission line action alternatives, no transmission line construction would occur on National Forest System or State lands between December 1 and April 30.

Effects of the alternatives were evaluated based on impacts on mountain goat habitat. The analysis area for direct and indirect project impacts on individuals and their habitat includes all mountain goat habitat in the Crazy, and Silverfish PSUs, and a 0.25-mile buffer surrounding the Rock Lake Ventilation Adit in the Rock PSU (Figure 90). The boundaries for determination of population trend and contribution toward population viability are the FWP Mountain Goat HD 100 and the KNF, respectively. Mountain goat habitat does not occur on private land within the zone of influence of the proposed project.

The impacts analysis includes an evaluation of the potential benefits to mountain goats from mitigation measures proposed by MMC or the agencies. The agencies' mitigations include funding for monitoring of mountain goat responses to mine-related impacts, prohibiting blasting at adit portals during kidding (between May 15 and June 15), access changes, land acquisitions, and prohibiting employees from carrying firearms.

3.25.3.4.2 Affected Environment

Mountain goats are found primarily in alpine habitat and high elevation coniferous forest stands throughout the year. Goats annually use the same summer and winter ranges, travel corridors, kidding areas, and mineral licks, and rarely explore new territory, which make them vulnerable to human activities or habitat changes in their range. Habitat use information and traditional use patterns are learned behaviors passed down through generations. If traditional use patterns are altered and seasonal home range knowledge is not transferred to offspring, then suitable ranges may not be recolonized. Mountain goats use steep rock outcrops and escarpments for escape from predators and security during the kidding period, and feed on vegetation found in the rock crevices. They use coniferous timber as shelter from severe weather, particularly during winter. Mountain goats eat a wide variety of foods, but in the Cabinet Mountains, shrubs are the major component of their diet year-round. Grasses are also consumed when available. The analysis area contains about 43,470 acres of summer mountain goat habitat ((Figure 90).

Mountain goat winter range is usually found in spruce-fir forests that are characterized by 80 percent slopes, average snow depths of less than 20 inches, or where the terrain extends to areas of lower elevation with an average snow depth less than 20 inches. During the winter, mountain goats usually forage on shrubs and trees. During mild winters, mountain goats have been known to travel between several winter areas. The analysis area contains about 5,863 acres of winter range (Figure 90).

During the 1988-1989 environmental studies, most goats in the area wintered in Rock Creek, but two were observed above Libby Creek and one above Ramsey Creek (Western Resource Development Corp. 1989f). FWP has identified the area above Rock Creek the south-facing slopes above upper West Fisher Creek; and south-facing slopes above Libby, Ramsey, and Poorman creeks as winter range (Brown 2006).

Historical population numbers were estimated to be 350 goats in the Cabinet Mountains in 1950, declining to between 95 and 160 in 1980 (Casebeer *et al.* 1950; Joslin 1980). Mountain goat counts have fluctuated widely during FWP standardized sampling surveys of HD 100 (Cabinet Mountains) since 2001. A low count of 53 total goats was counted in HD 100 in 2001 with a high count of 105 in 2003. The most recent count (2013) counted 54 total goats, but a high percentage of kids compared to adults (43 percent), indicating a high rate of reproduction (FWP 2013d). During surveys conducted in 1988 and 1989, 40 to 55 mountain goats were estimated to occupy rocky ridges in portions of the analysis area (Western Resource Development Corp. 1989f). During all seasons, most of the activity was in and near the headwalls of the Rock, Libby, and West Fisher creek drainages, but some solitary males were observed in the Ramsey and Poorman creek areas. The closest documented wintering area on the east side of the Cabinet Mountains was on the south-facing slope of Shaw Mountain in Libby Creek. Two goats were seen in this area in 1989 (Ibid.), which is about 0.5 mile north of the Libby Adit Site. More recent observations by FWP personnel indicate that Libby, Ramsey, West Fisher, Poorman, and Rock creeks represent a population epicenter for mountain goats in the southern Cabinet Mountains (Brown, pers. comm. 2008).

Mountain goat breeding occurs primarily in November (Joslin 1980). During the breeding season, mountain goats are primarily observed in the project vicinity in the Libby, Ramsey, and West Fisher creek drainages (Brown, pers. comm. 2007).

Summer transitional mountain goat habitat provides high-quality forage areas within high elevation coniferous forests and rock outcrops. Although winter range appears to be the limiting factor to goat densities in the Cabinet Mountains, quality summer range is also of paramount importance in providing highly nutritious forage, which fortifies the body for winter and sustains the population from year-to-year. Ridgelines are commonly used as travel corridors (Joslin 1980).

Mountain goats generally give birth to their kids in late May or early June on lower slopes at the mouth of drainages (Joslin 1980). The areas around Shaw Mountain and Leigh Lake appear to be important for mountain goat kidding (Brown, pers. comm. 2005, 2008).

3.25.3.4.3 Environmental Consequences

Mine Alternatives

Alternative 1 would have no direct impacts on mountain goats. Physical impacts on mountain goat habitat from the mine alternatives would be greatest for Alternative 2, which would affect 108 acres of summer range, primarily due to the Ramsey Plant Site and LAD Area 1. Alternative 2 would also directly affect 44 acres of winter range along Ramsey Creek. Alternatives 3 and 4 would directly impact 90 acres of summer mountain goat habitat along Libby Creek and at the Rock Lake Ventilation Adit. Alternatives 3 and 4 would not directly affect any winter mountain goat habitat.

In Alternatives 3 and 4, results of mountain goat surveys funded by MMC would be analyzed by the KNF, in cooperation with the FWP, at the end of the construction period to determine the appropriate level and type of survey work needed during the Operations Phase. If the agencies determined that construction disturbance were significantly affecting goat populations, mitigation measures would be developed and implemented to reduce the impacts of mine disturbance. MMC would not conduct any blasting at the entrance to any adit portals during May 15 to June 15 to avoid disturbance to the potential goat kidding area on Shaw Mountain.

Alternative A – No Transmission Line

Alternative A would have no impacts on mountain goat habitat (Table 208).

Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

The agencies' transmission line alternatives (C-R, D-R, and E-R) would not affect mountain goats. Construction of the Sedlak Park Substation and loop line would have no impacts to mountain goats with any alternative. Impacts on mountain goats from the Transmission Line Alternative B are shown in Table 208 and described in the following subsections. The analysis of the effects of human activity on goats is based on activity-specific buffers, and includes the effects of open roads. Road access changes associated with mitigation were determined for combined action alternatives. It is not possible to attribute these access changes to individual mine and transmission line alternatives independent of one another. Because the disturbance influence zone applied to new or opened roads associated with the transmission line is encompassed entirely by the buffer applied for helicopter disturbance, human disturbance effects for transmission line construction are calculated based on the area of overlap between the helicopter disturbance influence zone and mountain goat habitat. It is assumed that human activity would not affect mountain goats during transmission line operations. The evaluation of the effects of human activity on mountain goats from individual mine alternatives may be inferred from impact calculations for the combined mine-transmission line alternatives shown in Table 209.

Table 208. Mountain Goat Habitat Affected by North Miller Creek Transmission Line Alternative.

Habitat Component	[A] No Transmission Line (acres)	[B] North Miller Creek (acres)

[2] Ops = during project operations.
[3] Due to overlap between mine and transmission line disturbance footprints, habitat physically removed due to mine alternatives in combination with transmission line alternatives are not additive.
No transmission line construction would occur in any alternative between December 1 and April 30.
Source: GIS analysis by ERO Resources Corp. using KNF Cabinet Mountain goat habitat, 2006, developed by Jerry Brown, Montana Fish Wildlife and Parks, digitized by Barb Young.

Alternative B would physically remove 23 acres of summer mountain goat habitat and 24 acres of winter mountain goat habitat, due to the transmission line clearing area in Ramsey Creek (Table 208). During the Construction Phase, Alternative B would result in additional short-term disturbance to goats, primarily due to displacement from roads and helicopter line stringing in the Ramsey Creek area, between May 1 and November 30. Transmission line construction would not occur between December 1 and April 30. Line stringing conducted by helicopter would likely approach within 500 meters (horizontal distance) of mountain goat groups. Mountain goats within 500 meters of helicopter line stringing would be moderately to strongly disturbed (Côte *et al.* 2013). Disturbance to mountain goats would diminish with distance to 1,500 meters horizontal distance where little to no disturbance would occur (Côte *et al.* 2013). Disturbance could displace goats from suitable habitat or reduce their ability to effectively use the available habitat in the short term. Individual goats or groups could suffer increased stress levels from disturbance during helicopter line stringing, but these impacts would last no more than 10 days and would not likely affect goat populations. Disturbance effects could also occur from other transmission line construction activities in areas where helicopters were not used. Except for annual inspection and infrequent maintenance operations, helicopter and other transmission line construction activities would cease after transmission line construction until decommissioning. Helicopter use and other activities could result in short-term disturbance of mountain goats during line decommissioning.

Alternative C-R – Modified North Miller Creek Transmission Line Alternative

Alternative C-R would not physically remove any mountain goat habitat. Helicopter construction of transmission structures would not occur in proximity to mountain goat habitat, and is not expected to affect mountain goats. Line stringing conducted by helicopter may displace goats temporarily from suitable habitat or reduce their ability to effectively use the available habitat. During the Construction Phase, Alternative C-R would result in increased short-term disturbance of goat habitat, primarily due to helicopter line stringing at the mouth of upper Libby Creek. Individual goats may suffer increased stress levels from disturbance during helicopter line stringing, but these impacts would last no more than 10 days and would not likely affect goat populations. In Alternative C-R, except for annual inspection and infrequent maintenance operations, helicopter use and other transmission line construction activities would cease after transmission line construction until decommissioning, similar to Alternative B.

Alternative D-R – Miller Creek Transmission Line Alternative

Impacts of Alternative D-R on mountain goats would be the same as Alternative C-R.

Alternative E-R – West Fisher Creek Transmission Line Alternative

Impacts of Alternative E-R on mountain goats would be the same as Alternative C-R.

Combined Mine-Transmission Line Effects

Impacts of the combined mine-transmission line alternatives are shown in Table 209 and Table 210 and described below. Because some of the impact buffers for the mine alternatives and transmission line alternatives, acres of disturbance do not include areas of overlap from the different sources of disturbance. Construction of the Sedlak Park Substation and loop line would have no impacts to mountain goats with any alternative.

Alternative 2B would result in direct losses of about 125 acres of summer mountain goat habitat and 56 acres of winter mountain goat habitat, mostly due to disturbance from the Rock Lake Ventilation Adit and Ramsey Plant Site (Table 209). Slightly less goat habitat would be directly lost by the combined agencies' alternatives because the adits and plant site would be located in the same drainage (*i.e.*, Libby Creek). All combined agencies' alternatives would physically disturb about 90 acres of summer mountain goat habitat and no winter habitat. However, both Alternative 2B and the combined agencies' alternatives would directly impact one percent or less of the available summer and winter goat habitat.

Disturbance effects from human activity would have a much greater impact on the mountain goat than physical impacts on goat habitat, and would include disturbance from activities associated with blasting, construction of the plant and adit sites, road construction and use, plant and adit operations, and helicopter use that could displace goats from suitable habitat or reduce their ability to effectively use the available habitat. Disturbance from helicopter use and other transmission line construction activities are described above for the transmission line alternatives. Disturbance from blasting during mine construction could result in habitat displacement and increased stress levels for mountain goats, but would be short-term. Blasting would likely be mostly underground at the Libby Adit, where a maximum of two rounds of blasting would occur at the surface. The Ramsey Adits would probably require a maximum of two rounds of surface blasting per adit. The ventilation raise would be constructed from inside the mine and would not require any surface blasting, except for creation of the surface opening. Construction of the Ramsey Adits for Alternative 2B and the lower and upper Libby Adits for the combined agencies' alternatives is expected to take about 1 year. The Construction Phase in all combined action alternatives is expected to last 2 to 3 years. Noise and human activity associated with plant construction could also cause goats inhabiting surrounding areas to move to other portions of their home range for the duration of construction activities. Goats could suffer increased stress levels from disturbance during construction and operations that could result in a decline in reproductive rates (Joslin 1980).

During the Construction Phase, Alternative 2B would result in the most additional human disturbance to goat habitat, affecting about 6,791 acres of summer mountain goat range (16 percent of the habitat available). Human disturbance impacts from Alternative 2B would be greater than the combined agencies' alternatives due to helicopter line stringing, plant construction, and adit construction in Ramsey Creek. Less goat habitat would be disturbed by combined agencies' alternatives because the adits and plant site would be located in the same drainage (*i.e.*, Libby Creek), and because the transmission line would end at the mouth of Libby Creek. The agencies' alternatives would result in additional disturbance to between 5,006 acres and 5,066 acres or 12 percent of the summer mountain goat habitat available during project construction (Table 209). For the combined agencies' alternatives, no blasting would occur at the adits from May 15 to June 15, which would minimize disturbance to the potential goat kidding area on Shaw Mountain. The combined agencies' alternatives also would include funding for monitoring of mountain goat responses to mine-related impacts. In the agencies' mitigation (see section 2.5.7.4.5, *Indicator Species*), MMC would monitor goat populations, and the KNF, in consultation with the FWP, would assess effects. If mine disturbance were found to have a substantial impact on goat populations, MMC would develop, fund, and implement mitigation measures to reduce the impacts of mine disturbance.

During mine operations, additional disturbance to summer mountain goat habitat would range from 1,707 acres for the combined agencies' alternatives to 2,200 acres for Alternative 2B (4 and 5 percent of available summer habitat, respectively). Operations of Alternative 2B would affect slightly less winter goat habitat than the combined agencies' alternatives. During winter, mine operations would result in additional disturbance to winter mountain goat habitat ranging from

290 acres for Alternative 2B to 351 acres for the combined agencies' alternatives (5 and 6 percent of available winter habitat, respectively).Long-term disturbance to mountain goats during operations, such as noise and human activity, could cause goats to experience increased stress levels or to move from currently inhabited surrounding areas to other portions of their home range.

Most disturbances to goats would be short-term, and long-term disturbance (habitat removal) would increase on a relatively small proportion of goat habitat in the analysis area (Table 209). Alternative 2B would result in 0.3 percent of the summer mountain goat habitat and 1 percent of the winter mountain goat habitat available. The agencies' combined alternatives would result in less than 1 percent of the summer mountain goat habitat available and no loss of winter habitat. In all combined action alternatives, some disturbance effects would be offset by access changes (installation of gates or barriers and public access restrictions) and habitat acquisitions planned as mitigation for the impacts on grizzly bear and big game security. Acquired parcels would be managed for grizzly bear use in perpetuity, and could improve or contribute suitable mountain goat habitat if the acquired parcels were located within goat habitat. The combined agencies' alternatives would include more road access changes and habitat acquisition, and would more effectively mitigate potential effects of disturbance to mountain goats. The combined mine-transmission line alternatives are not anticipated to result in the loss of goat herd occurrence or abundance in the southern Cabinet Mountains. In all combined action alternatives, the risk of mountain goat mortality would increase as a result of increased access to summer mountain goat habitat.

Cumulative Effects

Past actions are described in section 3.2, *Past and Current Actions,* shown on Figure 50, and listed in Appendix E. Past actions, particularly timber harvest. Past actions (Appendix E) applicable to cumulative effects on mountain goats include mineral activities and road construction, maintenance and obliteration.

Neither Alternative 1 nor Alternative A would cumulatively impact mountain goats. Mineral exploration has occurred and would continue to occur throughout the Cabinet Mountains, cumulatively displacing goats from suitable habitat or reducing their ability to effectively use the available habitat. Disturbance impacts on mountain goats from the combined action alternatives would be compounded when impacts from other reasonably foreseeable actions are taken into account. Although unlikely to occur concurrently, the Wayup Mine/Fourth of July Road Access Project, the Rock Creek Project, and the Bear Lakes Access Project would collectively influence about 4,561 acres of MS-1 goat habitat (Bratkovich, pers. comm. 2008), potentially resulting in this habitat becoming less desirable or less effective for mountain goats.

Some of the disturbance associated with construction of the proposed project and other reasonably foreseeable actions, such as blasting and helicopter line stringing and construction, would be short-term. Noise generated by construction and blasting for the evaluation adits for the Rock Creek Project would occur sporadically for several weeks. Underground blasting would be considered after the adit reaches a depth of about 500 feet at the Rock Creek site to reduce the effects of blasting, based on experience at the Troy Mine adit. If surface blasting and other construction activities occurred concurrently for the Rock Creek and Montanore projects, cumulative noise disturbance could result in habitat displacement and increased stress levels for mountain goats.

While cumulative disturbance impacts on goats would be mostly short-term, disturbance during project operations, such as noise and human activity, would be long-term. Road access into critical goat habitat is the single biggest threat to goats in the Cabinet Mountains (Joslin 1980), and the Fourth of July proposal would construct a new road to the edge of the CMW and MS-1 habitat. Cumulative long-term disturbance to mountain goats could result in changes in seasonal habitat use, potentially causing goats to shift their use of both summer and winter habitat in Ramsey Creek (Alternative 2B only), and summer ranges in Libby Creek (all combined action alternatives), upper West Fisher Creek and Rock Creek basins. These potential changes in seasonal habitat use could increase the use of unaffected summer ranges creating potential conflicts with resident goats in the CMW. The cumulative disturbance effects of the mine alternatives and other reasonably foreseeable actions could result in reduced reproductive rates and a decrease in population of the Rock Creek herd. Some cumulative human-caused disturbance effects would be offset by road access changes (installation of barriers and gates and public access restrictions) and habitat acquisitions planned as mitigation for the Montanore, Rock Creek, and other projects.

No other past, current, or reasonably foreseeable actions are anticipated to contribute to cumulative impacts on mountain goats.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8. In these alternatives, MMC did not propose to implement feasible measures to minimize effects on the mountain goat or practicable measures to maintain and protect wildlife habitat. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would incorporate feasible and practicable measures to minimize adverse environmental impacts on the mountain and wildlife habitat. These measures would include adding timing restrictions to blasting, and implementing monitoring and adaptive management during construction and operations. The agencies' land acquisition requirements in Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R would more likely provide mountain goat habitat than the land acquisition requirements of Mine Alternative 2 and Transmission Line Alternative B.

National Forest Management Act/Kootenai Forest Plan

The KFP does not provide specific direction for mountain goats. In all combined mine-transmission line alternatives, adequate amounts of mountain goat habitat would continue to be provided for mountain goats. All combined mine-transmission line alternatives would be consistent with KFP direction on MIS (KFP Vol. I, II-1 #3 and #, pp. II-1#3, II-2#12, and II-23-23.

Based on the analysis for mountain goat and the KNF Conservation Plan (Johnson 2004a), in all action alternatives, habitat for alpine habitat species would be provided in sufficient quality and quantity of the diverse age classes of vegetation needed for viable populations.

Forest Service Management Indicator Species Statement of Findings

All of the action alternatives would have a minor long-term effect on mountain goats. Less than 0.3 percent of the available summer habitat would be directly lost from the construction of any alternative. About 1.2 percent of the available winter habitat would be directly lost from the construction of Alternative 2B. Operational activities of the mine under Alterative 2B could displaces goats from 5.1 percent of the available summer and winter habitat, whereas, the agencies' modified alternative could displace goats from about 3.9 and 6.2 percent of available summer and winter habitat, respectively. Mosaics of habitat types, forage opportunities, and secure habitat away from open roads and mine facilities are available within alpine habitats in the analysis area. ***Therefore, sufficient quality and quantity of the diverse age classes of vegetation currently found within the analysis area would be available for mountain goats in the Crazy and Silverfish PSUs to maintain a viable population.***

State Requirements

Alternatives 3 and 4 would comply with the MMRA regarding disturbed lands being reclaimed to a post-mining land use with stability and utility comparable to that of the pre-mining landscape. Draft findings regarding compliance with MFSA requirements are discussed in the Summary, beginning on p. S-53. Hunting is managed by the FWP. Proposed actions would not prevent the state from continuing to manage these species as harvestable populations.

3.25.3.5 Pileated Woodpecker

3.25.3.5.1 Analysis Area and Methods

Pileated woodpecker is the MIS for old growth and snag habitat on the KNF. Old growth habitat provides both nesting habitat and year-round foraging habitat for pileated woodpecker (Thomas 1979). Large diameter snags characteristically found in old growth forests provide nesting habitat for this species (the largest woodpecker in the Rocky Mountains), while both the snags and coarse woody debris provide habitat for the woodpecker's primary prey species, the carpenter ant (Warren 1990).

Pileated woodpecker population ecology, biology, habitat description, and relationships in the northern Rocky Mountains are described in McClelland and McClelland (1999), McClelland (1979, 1977), McClelland *et al.* (1979), and Warren (1990). Research conducted in the Pacific and Inland Northwest is described in Bull and Jackson (1995), Bull and Holthausen (1993), Bull *et al.* (1992b), Bull (1987, 1980, 1975), Bull and Meslow (1977), Mellen *et al.* (1992), Mellen (1987), Thomas (1979), Mannan (1977), and Jackman (1974). This research provided guidance in evaluating potential habitat and effects to pileated woodpeckers and is incorporated by reference.

Pileated woodpecker occurrence data come from recent District wildlife observation records, the Region One Landbird Monitoring Program (Avian Science Center, University of Montana), and Forest historical data (NRIS Wildlife). Potential habitat for this species on National Forest System land was estimated using designated and undesignated old growth habitat and replacement old growth habitat that has been mapped for the KNF. General pileated woodpecker habitat was identified using KNF vegetation data. Often specific pileated woodpecker habitat information was not available for private or state-owned lands in the analysis area, much of which has been logged in the past 20 to 30 years.

The analysis area includes the PSUs impacted by proposed activities. While the bulk of activities occur within the Crazy and Silverfish PSUs, there are also project activities within McElk, Riverview, Treasure, and Rock PSUs. The analysis area boundary for direct effects is the proposed activity areas, as activities and alteration of the habitat would affect suitability for different species. The acres directly impacted by activities are put into the context of the PSU scale to provide a consistently sized analysis unit and better gauge the relative impacts of the activities. The boundaries for indirect and cumulative effects are the planning subunits that contain the analysis area as alteration of habitat could affect the availability and use of habitats. Analysis at the PSU scale allows the effects of the proposed activities to be put into context and their relative impacts gauged. The impacts to the Rock PSU are limited to a less than 1 acre of patch of steep, rocky ground, the impacts are nearly undetectable at the PSU scale, and therefore this PSU is not carried forward in detailed analysis.

Project impacts are evaluated based on impacts to important attributes of pileated woodpecker habitat, primarily impacts to designated and undesignated old growth habitat. Specific features of old growth stands evaluated for project impacts include preferred nest tree species, preferred nest tree size, down logs (both size and quantity), basal area, and canopy closure.

The overall assessment of habitat quality also accounts for potential adverse factors discussed in the old growth habitat analysis that relate to size and connectivity, and include fragmentation, edge effect, and lack of interior habitat. Risk to firewood cutting is also evaluated. Other stands (not designated as old growth) may have one or more important attributes of old growth forests, or perhaps provide for connectivity and interior habitat. These stands were also reviewed as part of this analysis. The impacts analysis includes an evaluation of the potential benefits to pileated woodpeckers from mitigation measures proposed by MMC or the agencies, such as designation of old growth-associated with the agencies' proposed old growth mitigation and land acquisitions.

3.25.3.5.2 Affected Environment

No population estimate is available for pileated woodpeckers within the KNF. However, trend data for many species, including the pileated woodpecker are being gathered through the Northern Region Landbird Monitoring Program. The objective of this program is long-term population-trend monitoring on the National Forests in Region One. Seven surveys have been conducted over a 10-year period on the KNF (USDA Forest Service 2008d).

Within the Crazy and Silverfish PSU, no pileated woodpeckers were observed during breeding bird surveys conducted in 2005 at the Little Cherry Creek Tailings Impoundment Site, the Ramsey Plant Site, the LAD Areas, and MMC's proposed transmission line alignment (Westech 2005a). The pileated woodpecker has been documented in the Crazy and Silverfish PSUs during 1995, 1996, 2000, 2004, 2007, and 2012 during different bird surveys conducted by either the MNHP, the Avian Science Center as part of the Region 1 Landbird monitoring program, and most recently the Rocky Mountain Bird Observatory monitoring program which has replaced the previous Region 1 Landbird Monitoring program. Data gathered through the Regional bird monitoring programs, do not indicated any noticeable population change for the species on the KNF (USDA Forest Service 2008d).

The Crazy PSU contains 8,373 acres of effective old growth habitat (both designated and undesignated), and the Silverfish PSU contains 5,887 acres of effective old growth habitat (both designated and undesignated). The Crazy PSU contains 465 acres of replacement old growth habitat (both designated and undesignated), and the Silverfish PSU contains 1,506 of replacement old growth habitat (both designated and undesignated). Existing pileated woodpecker nesting territories likely encompass a large portion of this old growth habitat. Snags and down wood provide food resources such as carpenter ants and their larvae, one of the primary prey items for pileated woodpeckers in the Northern Rockies (McClelland and McClelland 1999; McClelland 1977). Existing snag densities and amounts of down wood in the Crazy and Silverfish PSUs are greater than KFP-recommended levels. Existing PPL for snag habitat and are 73 percent in the Crazy PSU and 90 percent in the Silverfish PSU (KFP recommended level is 40 percent PPL) (see 3.25.2, *Key Habitats*).

3.25.3.5.3 Environmental Consequences

The following section discusses the direct and indirect, and cumulative effects on pileated woodpeckers for each of the mine alternatives, transmission line alternatives, and combined mine-transmission line alternatives, on federal and private land. Impacts on pileated woodpecker in the Crazy and Silverfish PSUs from the mine and transmission line alternatives are summarized in Table 211 and Table 212 and described below.

Alternative 1 – No Mine

In Alternative 1, natural successional processes would continue to occur throughout old growth stands and habitat would continue to be provided for pileated woodpecker nesting pairs where feeding and breeding conditions are suitable. There would be no direct impacts on pileated woodpecker (old growth habitat) from Alternative 1 (Table 211).

Replacement old growth habitat currently provides less suitable stand conditions for territory occupation. Over the next several decades, in the absence of catastrophic fires or windstorms, these stands would develop habitat features suitable for pileated woodpeckers such as larger trees, larger snags, more down logs, and more dead and dying trees that provide food resources such as carpenter ants and their larvae.

In Alternative 1, an indirect effect of continued disruption of the historical pattern of frequent fires in the drier ponderosa pine/Douglas-fir cover type would be ecological changes, such as the encroachment of Douglas-fir saplings in the understory. Eventually, these sites would develop a higher percentage of Douglas-fir trees, snags, and down logs more suitable as foraging habitat for pileated woodpeckers. This successional trend may result in a reduction in quality pileated woodpecker nest trees (ponderosa pine) since Douglas-fir was not found to be important for pileated woodpecker nest cavity excavation in the northern Rocky Mountains (McClelland and McClelland 1999; McClelland 1977; Weydemeyer and Weydemeyer 1928), in northeast Oregon (Bull 1987, 1975; Thomas 1979), or in British Columbia (Harestad and Keisker 1989).

Table 211. Effects on Potential Pileated Woodpecker Habitat and Population Index in Crazy PSU by Mine Alternative.

Analysis Area	[1] No Mine/ Existing Conditions	[2] MMC's Proposed Mine	[3] Agency Mitigated Poorman Impoundment Alternative	[4] Agency Mitigated Little Cherry Creek Impoundment Alternative
Unmitigated Effects				
Effective OG (acres)	8,373	8,072 (301)	8,219 (154)	8,197 (176)
Replacement OG (acres)	465	418 (47)	465 (0)	418 (47)
General pileated woodpecker habitat	8,788	8,584 (204)	8,720 (68)	8,649 (139)
Mitigated Effects				
Total old growth designated for mitigation (acres)[1]	NA	NA	797	828

OG = old growth.
Number in parentheses is the reduction in habitat acres due to the alternative compared to Alternative 1 No Mine/Existing Conditions.
Mine alternatives would not impact potential pileated woodpecker habitat (old growth) in the Silverfish PSU and are not shown.
[1] Old growth designated to mitigate impacts on old growth. See section 2.5.7.4.4, *Key Habitats* for a more detailed description of old growth mitigation.

Alternative 2 – MMC's Proposed Mine

As shown in Table 211, Alternative 2 would affect about 301 acres of effective old growth habitat, 47 acres of replacement old growth, and 204 acres of general habitat in the Crazy PSU, reducing nesting and foraging habitat and habitat quality for the pileated woodpecker. No effective or replacement old growth would be directly affected by Alternative 2 in the Silverfish PSU or on private or State land east of the Silverfish PSU. The majority of impacts on potential pileated woodpecker habitat would occur in Little Cherry Creek Impoundment and LAD Area 2 at the mouth of Ramsey and Poorman creeks, reducing habitat connectivity between these drainages. Several old growth blocks would be reduced in size, diminishing their capacity to support pileated woodpeckers. The Alternative 2 tailings impoundment would result in the loss of 158 acres of effective old growth, 47 acres of replacement old growth, and 172 acres of general pileated woodpecker habitat in one localized area, which could displace one or more nesting pairs that may have traditionally used the area. Old growth impacts associated with Alternative 2 could include the removal of a nest tree or night winter roost tree used by the pileated woodpecker. Impacts on old growth habitat are described in section 3.22.2, *Old Growth Ecosystems*. Loss of old growth providing potential pileated woodpecker habitat may be offset by private land acquisition associated with grizzly bear habitat mitigation. As described in section 3.25.2.2, *Snags and Woody Debris*, Alternative 2 would result in the loss of snags greater than 20 inches diameter at breast height (dbh) and down logs greater than 10 inches dbh that provide potential nesting and foraging habitat for pileated woodpeckers. Snag densities and quantities of down wood would remain greater than KNF-recommended levels and would continue to be sufficient to sustain viable populations of cavity-dependent species on the KNF. Snag losses would not likely increase due to roads constructed for Alternative 2 because these roads would be closed to the public.

Table 212. Effects on Potential Pileated Woodpecker Habitat and Population Index by Transmission Line Alternative.

Analysis Area and Indicator	[A] No Transmission Line	[B] North Miller Creek	[CR] Modified North Miller Creek	[DR] Miller Creek	[ER] West Fisher Creek

Crazy and Silverfish PSUs					
Mitigated Effects					
Total old growth designated for mitigation (acres)[1]	NA	0	29	12	6

OG = old growth.
Number in parentheses is the reduction in habitat acres due to the alternative compared to Alternative A, No Transmission Line.
[1] Old growth designated to mitigate impacts on old growth. See section 2.5.7.4.4*, Key Habitats* for a more detailed description of old growth mitigation.
Source: GIS analysis by KNF.

Noise and other human-caused disturbances, such as blasting, construction of the plant and adit sites, road construction and use, and plant and adit operations could cause pileated woodpeckers to avoid nearby habitat, at least temporarily. Disturbance impacts would likely be greatest during the Construction Phase, but could persist through mine operations.

Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Direct impacts of Alternative 3 on old growth habitat potentially supporting pileated woodpeckers would be similar to Alternative 2, except that Alternative 3 would affect less old growth. About 154 acres of effective old growth and 68 acres of general pileated habitat in the Crazy PSU would be disturbed In Alternative 3 (Table 211). The majority of impacts on designated old growth would occur as a result of the Poorman Impoundment construction or in LAD Area 2 at the mouth of Ramsey and Poorman creeks, reducing habitat connectivity between these drainages. Several old growth blocks would be reduced in size, diminishing their capacity to support pileated woodpeckers. The Alternative 3 tailings impoundment would result in the loss of 117 acres of effective old growth and 60 acres of general pileated woodpecker habitat in one localized area, which could displace one or more nesting pairs that may have traditionally used the area. Old growth impacts associated with Alternative 3 could include the removal of a nest tree or night winter roost tree used by the pileated woodpecker or some of the old growth-associated wildlife species it represents.

The agencies' mitigation in Alternative 3 would include the designation of 797 acres of additional old growth on National Forest System lands. Designation of additional areas of old growth would not create new old growth, but would ensure that these areas are managed to retain or develop old growth characteristics, potentially improving the quality of habitat for pileated woodpeckers. Loss of old growth providing potential pileated woodpecker habitat also may be offset by private land acquisition associated with grizzly bear habitat mitigation.

Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Impacts of Alternative 4 on old growth habitat potentially supporting pileated woodpeckers would be similar to Alternative 2, except that Alternative 4 would affect less old growth. Alternative 4 would affect about 176 acres of effective habitat, 47 acres of replacement habitat, and 139 acres of general pileated habitat in the Crazy PSU (Table 211).

Impacts from noise and human activities associated with Alternative 4 would be similar to Alternatives 2 and 3.

The Alternative 4 tailings impoundment would result in the loss of 135 acres of effective old growth, 47 acres of replacement old growth, and 133 acres of general pileated woodpecker habitat in one localized area, which could displace one or more nesting pairs that may have traditionally used the area. Old growth impacts associated with Alternative 4 could include the removal of a nest tree or night winter roost tree used by the pileated woodpecker or some of the old growth-associated wildlife species it represents.

Alternative 4 would include the designation of 828 acres additional old growth on National Forest System lands. Designation of additional areas of old growth would not create new old growth, but would ensure that these areas are managed to retain or develop old growth characteristics, potentially improving the quality of habitat for pileated woodpeckers. Also, loss of old growth providing potential pileated woodpecker habitat may be offset by private land acquisition associated with grizzly bear habitat mitigation.

Alternative A – No Transmission Line

There would be no impacts on pileated woodpecker from Alternative A (No Transmission Line) (Table 212). There will be no impacts to the Riverview PSU from any of the transmission line alternatives. Based on the lack of old growth habitat and pileated woodpecker sightings, construction of the Sedlak Park Substation and loop line would not affect pileated woodpeckers in any transmission line alternative.

Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

Alternative B would affect about 12 acres of effective old growth habitat in the Crazy PSU and 9 acres of general pileated habitat (Table 212). No replacement old growth would be impacted in the Crazy PSU and no effective or replacement old growth would be impacted in the Silverfish or Riverview PSUs. Alternative B would impact about 6 acres of pileated habitat on Plum Creek land in the McElk PSU. The majority of impacts on old growth would occur in the Ramsey Creek corridor and at the confluence of Libby and Howard creeks, reducing habitat connectivity in these drainages. Reducing the size of old growth blocks would diminish their capacity to support pileated woodpeckers. Loss of old growth providing potential pileated woodpecker habitat may be offset by private land acquisition associated with grizzly bear habitat mitigation.

As described in section 3.25.2.2, *Snags and Woody Debris*, Alternative B would result in the loss of snags greater than 20 inches dbh and down logs greater than 10 inches dbh that provide potential nesting and foraging habitat for pileated woodpeckers. Snag densities and quantities of down wood would remain greater than KNF-recommended levels and would continue to be sufficient to sustain viable populations of cavity-dependent species in the KNF. Snag losses would not likely increase due to roads constructed for Alternative B because these roads would be closed to the public.

Noise from helicopters during line stringing could cause pileated woodpeckers to avoid nearby habitat, at least temporarily. Similar effects could occur from other transmission line construction activities in areas where helicopters were not used, and would be more extensive for Alternative B than the agencies' alternatives. Disturbance impacts would be short-term and, with the exception of line maintenance activities, would cease after transmission line construction until decommissioning. Helicopter use and other activities would cause similar disturbances with similar durations during line decommissioning.

Alternative C-R – Modified North Miller Creek Transmission Line Alternative

Alternative C-R would have similar physical impacts on pileated woodpecker habitat as Alternative B, except that no effective or replacement old growth would be disturbed in the Crazy or Silverfish PSUs. As shown in Table 212, Alternative C-R would affect 12 acres of general pileated habitat in the Crazy PSU and 3 acres of general habitat in the Silverfish PSU. Additionally, 6 acres of State land would be impacted in the Silverfish PSU and 10 acres of Plum Creek land in the McElk PSU would be impacted. Reducing the size of old growth blocks would diminish their capacity to support pileated woodpeckers. The majority of impacts on old growth would occur at the confluence of Libby and Howard creeks, reducing habitat connectivity between these drainages. Alternative C-R would include the designation of 29 acres of additional old growth on National Forest System lands. Designation of additional areas of old growth would not create new old growth, but would ensure that these areas are managed to retain or develop old growth characteristics, potentially improving the quality of habitat for pileated woodpeckers. Impacts on old growth on private and State lands would be minimized through implementation of the Environmental Specifications (Appendix D) and Vegetation Removal and Disposition Plan. Loss of old growth providing potential pileated woodpecker habitat may also be offset by private land acquisition associated with grizzly bear habitat mitigation.

Impacts on snag habitat from Alternative C-R would be similar to Alternative B, except that disturbance would be more extensive for Alternative C-R (see section 3.25.2.2, *Snags and Woody Debris*).

Alternative D-R – Miller Creek Transmission Line Alternative

Impacts of Alternative D-R on old growth habitat potentially supporting pileated woodpeckers would be similar to Alternative C-R. As shown in Table 212, Alternative D-R would directly affect 2 acres of effective old growth habitat. There would be no impact on replacement old growth in the Crazy PSU. General pileated habitat would be reduced by 27 acres in the Crazy

PSU. Alternative D-R would have no effect on effective or replacement old growth habitat in the Silverfish PSU. Thirty-six acres of general pileated habitat would be impacted. Alternative D-R would include the designation of 12 acres of additional old growth on National Forest System lands. Impacts on snag habitat from Alternative D-R would be similar to Alternatives B and C-R, except that disturbance would be more extensive for Alternative D-R (see section 3.25.2.2, *Snags and Woody Debris*).

Noise and other human-caused disturbance to pileated woodpeckers would be similar to Alternative C-R, except that disturbance would be more extensive for Alternative D-R.

Alternative E-R – West Fisher Creek Transmission Line Alternative

Direct impacts on pileated woodpecker habitat from Alternative E-R would be similar to Alternative D-R, a 2 acre reduction in effective old growth and a 27 acre reduction in general pileated habitat in the Crazy PSU. There would be no impact on replacement old growth habitat in the Crazy PSU. In the Silverfish PSU, 52 acres of general pileated habitat, 17 acres of habitat on State of Montana land, and 3 acres of Plum Creek land would be impacted. In the McElk PSU 10 acres of Plum Creek land would be impacted. Alternative E-R would include the designation of 6 acres of additional old growth on National Forest System lands. Noise and other human-caused disturbance to pileated woodpeckers on private and State land would be similar for Alternatives E-R and Alternatives C-R and D-R, except that the extent of the disturbance would be greater for the longer Alternative E-R.

Combined Mine-Transmission Line Effects

Impacts on pileated woodpecker in the Crazy, Silverfish, and McElk PSUs from the combined mine-transmission line alternatives are summarized in Table 213. There are no impacts to the Riverview PSU from any of the alternative combinations. Based on the lack of old growth habitat and pileated woodpecker sightings, construction of the Sedlak Park Substation and loop line would not affect pileated woodpeckers in any transmission line alternative.

In the Crazy PSU, MMC's proposed alternative (2B) impacts 313 acres of effective old growth, 47 acres of replacement old growth, and 213 acres of general pileated woodpecker habitat. The agencies' combined alternatives will impact between 154 and 156 acres of effective old growth, 0 acres of replacement old growth, and 80 to 95 acres of general pileated habitat for the Poorman Impoundment Alternatives. Under the Little Cherry Creek Impoundment Alternatives, between 176 and 178 acres of effective old growth, 0 to 47 acres of replacement old growth, and 151 to 166 acres of general pileated habitat will be impacted.

In the Silverfish PSU none of the alternatives impact effective or replacement old growth habitat. The alternatives that include the Poorman Impoundment would impact between 3 and 52 acres of general pileated habitat, 6 to 17 acres of state of Montana land, and 0 to 10 acres of Plum Creek land. Under the alternatives that include the Little Cherry Creek impoundment no effective or replacement old growth habitat will be impacted, between 3 and 52 acres of general pileated habitat, 6 to 17 acres of State of Montana land, and 0 to 3 acres of Plum Creek land will be impacted.

In the McElk PSU each of the agency combined alternatives impacts 10 acres of Plum Creek land. The MMC alternative impacts 6 acres of Plum Creek land. There are no impacts to the Riverview PSU from any of the alternative combinations.

OG = old growth.
Number in parentheses is the reduction in habitat acres due to the alternative compared to Alternative 1, No Mine/Existing Condition.
[1] Old growth designated to mitigated impacts on old growth. See 2.5.7.4.4, *Key Habitats* for a more detailed description of old growth mitigation.
Source: GIS analysis by KNF.

For all combined action alternatives, the tailings impoundment would result in the loss of 117 to 158 acres of effective old growth, 0 to 47 acres of replacement old growth, and 60 to 172 acres of general pileated habitat in one localized area, which could displace one or more nesting pairs that may have traditionally used the area. Old growth impacts associated with all combined action alternatives could include the removal of a nest tree or night winter roost tree used by the pileated woodpecker. Impacts on old growth from the combined mine-transmission line alternatives are described in section 3.22.2*, Old Growth Ecosystems*.

As described in section 3.25.2.2, *Snags and Woody Debris*, all combined action alternatives would result in the loss of snags greater than 20 inches dbh and down logs greater than 10 inches dbh that provide potential nesting and foraging habitat for pileated woodpeckers. In all combined mine-transmission line alternatives, snag densities and quantities of down wood would remain greater than KNF-recommended levels and would continue to be sufficient to sustain viable populations of cavity-dependent species in the KNF. Snag losses would not likely increase due to roads constructed for the combined action alternatives because these roads would be closed to the public.

In all combined action alternatives, noise from helicopters during line stringing and from other construction-related activities may cause pileated woodpeckers to avoid nearby habitat, at least temporarily. Disturbance impacts from blasting and helicopters would be short-term and, with the exception of line maintenance activities, would cease after transmission line construction until decommissioning. Disturbance from helicopter use and other transmission line construction activities are described for Alternatives B and C above. Disturbance impacts during mine operations would probably be lower in intensity, but would last through the life of the mine.

The agencies' alternatives would include the designation of between 802 and 857 acres of additional old growth on National Forest System lands (see section 2.5.7.4.4, *Key Habitats*), potentially improving habitat for an additional breeding pair of pileated woodpeckers. Designation of additional areas of old growth would not create new old growth, but would ensure that these areas are managed to retain or develop old growth characteristics, potentially improving habitat quality for pileated woodpeckers. For all combined action alternatives, impacts on old growth on private land would be minimized through implementation of the Environmental Specifications (Appendix D) and Vegetation Removal and Disposition Plan described in section 2.5.2.5.2, *Vegetation Removal and Disposition Plan*. In all combined action alternatives, losses and degradation of providing potential pileated woodpecker habitat may be offset by private land acquisition associated with grizzly bear habitat mitigation.

Cumulative Effects

Summary of Existing Condition

Past actions, particularly timber harvest, road construction, and fire-suppression activities, have altered the old growth ecosystems in the analysis area. These changes have resulted in a reduction in late succession habitats; conditions favoring shade-tolerant, fire-intolerant species; loss of large snags and down wood; and increases in tree density and a shift to a largely mid-seral structural stage (USDA Forest Service 2003b).

Timber harvest has occurred in the analysis area since the 1950s. Prior to the 1990s, timber harvest often resulted in the loss of old growth, snags and down wood habitat. Road construction reduced the availability of snags and downed wood both directly and from firewood collection.

Detailed description of previous vegetation and road management activities are found in Appendix E, of this document. In unharvested areas, natural disturbances such as wildfire would have resulted in the development of complex forest structure used by pileated woodpeckers. In contrast, fire suppression since the early 1900s has altered stand structure resulting in more homogenous stands with increased fuel loading in the understory and reduced development of large diameter trees, snags, and down woody materials. Since the 1990s, application of KFP standards has resulted in the retention of snags and down woody materials as well as protection of old growth habitat. Also, there has been more reliance on intermediate harvest that leaves more forest structure (including large old trees) and cover.

Effects of No Action alternatives

The no action alternatives do not directly contribute any cumulative effects to pileated woodpeckers or their habitat.

Effects of Ongoing and Reasonably Foreseeable actions

Reasonably foreseeable actions include those federal, state, or private activities that are ongoing or scheduled to occur within the next five years, independent of this federal action. Appendix E identifies those current and foreseeable actions in the analysis area that were determined to be appropriate for inclusion in the analysis of environmental effects.

As described above, loss of pileated habitat due to past actions has occurred within the analysis area. However, potential pileated habitat occurs throughout the analysis area due to the moist environment and associated forest cover types found here. Changes in harvest methods and protection of old growth areas in recent years has created/maintained higher quality habitat throughout the analysis area.

Vegetation Management and Fuels Reduction Activities

Regeneration harvest included in the Miller-West Fisher Vegetation Management Project, the Coyote Improvement Vegetation Management Project, and the Silverbutte Bugs timber sale, which would occur in the Silverfish PSU, would not directly affect old growth providing potential pileated woodpecker habitat. Cumulatively, the proposed action alternatives activities in designated and undesignated old growth would not reduce the amount and distribution of old growth below KFP requirements.

Public Use

Firewood gathering would continue to remove some snags from old growth along open road corridors and these acres were previously accounted for as part of the existing condition. Other forest uses such as mushroom and berry picking, camping, hunting, Christmas tree cutting, bough collection, etc. have little to no measurable impact on old growth and the pileated woodpecker because they are largely non-consumptive or rapidly re-established and would not contribute to the cumulative effect on snags and the old growth resource

While the combined action alternatives, in combination with other past, current, and reasonably foreseeable actions, would result in minimal losses and degradation of pileated woodpecker habitat. In addition, mitigation associated with combined agencies' alternatives would increase the proportion of designated old growth and promote the maintenance or development of pileated woodpecker habitat in the analysis area.

Private Lands

Development of private lands, including timber harvest, home construction, and land clearing, are likely to continue within the Crazy and Silverfish PSUs. Therefore, on private and State lands there would likely be a decrease in at least general forest habitat. Impacts on pileated woodpecker on private, corporate timberlands and State lands would probably be minimal because it is likely that limited amounts of old growth occur on these lands, based on development and past and current harvest practices.

Cumulative noise and other human-caused disturbances could occur as a result of the combined action alternatives and other reasonably foreseeable actions. Cumulative disturbance effects could affect individual pileated woodpeckers, but would not likely affect pileated woodpecker populations in the KNF.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8. In these alternatives, MMC did not propose to implement feasible measures to minimize effects on the mountain goat or practicable measures to maintain and protect wildlife habitat. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would incorporate feasible and practicable measures to minimize adverse environmental impacts on the mountain and wildlife habitat. These measures would include adding timing restrictions to blasting, and implementing monitoring and adaptive management during construction and operations. The agencies' land acquisition requirements in Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R would more likely provide mountain goat habitat than the land acquisition requirements of Mine Alternative 2 and Transmission Line Alternative B.

National Forest Management Act/Kootenai Forest Plan

1. Forestwide Management Direction – KFP II-1 #7, #8, II-22-23
a. #7 – *Maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species:* The action alternatives would be consistent with KFP direction to maintain diverse age classes of vegetation for viable populations because the reduction in potential old growth habitat would be 3 percent (313 acres in Alternative 2) and the reduction in general pileated woodpecker habitat would be 5 percent (213 acres in Alternative 2) or less.

b. #8 – *Manage for sufficient snags and snag replacement trees to maintain viable populations of snag-dependent species:* Snag density would remain at 71 percent in the Crazy PSU and 72 percent in the Silverfish PSU and are better than the recommended 40 and 60 percent levels (see Cavity Habitat section). All action alternatives would be consistent with KFP direction for snags and down wood (see section 3.25.2.2, *Snags and Woody Debris*). In all combined mine-transmission line alternatives, a wide range of successional habitats and associated amounts of down wood would be available.

c. 22 – *Maintenance of 10 percent of the KNF land base below 5,500 feet in old growth condition that is representative of the major forest types, spread evenly through most major drainages, and providing for old-growth dependent wildlife species:* All combined mine-transmission alternatives would require a project-specific amendment to change the current MA 13 allocation of all old growth that would be harvested either as a result of transmission line construction to MA 23 (Electric Transmission Corridor) or as a result of mine related facility or impoundment development or MA 31 (Mineral Development) (See Forest Plan section)

MA 13). All action alternatives would be consistent with KFP direction to maintain a minimum of 10 percent old growth below 5,500 feet in elevation in each third order drainage or compartment, or a combination of compartments.

Analysis of old growth forest-wide (USDA Forest Service2012c) concludes that at least 10 percent of the KNF below 5,500 feet is managed as old growth, as required in the KFP. Specifically, National Forest System lands below 5,500 feet include 298,348 acres (16 percent) of old growth or replacement old growth. About 10.8 percent (201,472 acres) of those lands were determined to be effective old growth, and 5.2 percent (96,876 acres) were identified as replacement old growth.

The action alternatives would result in between 16.8 and 16.9 percent designated old growth below 5,500 feet elevation in the Crazy PSU, and 13.6 percent designated old growth below 5,500 feet elevation in the Silverfish PSU. The KFP established that maintaining 10 percent of old growth habitat is sufficient to support viable populations of old-growth dependent species (KFP Vol. 1, II-1 #7 and III-54; Vol. 2, A-17).

d. 22, 23 – Maintenance of viable populations of existing native and desirable nonnative vertebrate species, as monitored through indicator species, attained through the maintenance of a diversity of plant communities and habitats: See 1.a. above for habitat diversity. The pileated woodpecker is monitored as an indicator species for snag and old growth habitats. Their occurrence and estimation of population is monitored through District observations, Region One Landbird monitoring effort, and KNF Monitoring and Evaluation Reports.

2. Appendix 12 – Management indicator species: See 1.d. above.

3. Appendix 16 – Cavity Habitat (Snags and Down Wood): For cavity habitat, see 1.b. above. Retention of recommended tons/acre of coarse woody debris would be met by following Graham *et al.* (1994) and emphasizing the retention of larger diameter pieces where available and snags felled for safety.

4. Appendix 17 and Kootenai FSM 2432.22 Supplement No. 85 – Old Growth: See 1c.above and the Old Growth section.

National Forest Management Act: The combined mine alternatives comply with NFMA direction to provide diverse populations of plant and animal communities by following KFP standards and guidelines (Johnson 2004a).

Forest Service Management Indicator Species Statement of Findings

KFP direction is to "maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species,… in sufficient quality and quantity to maintain viable populations" (KFP Vol. 1, II-1 #7). Based on the pileated woodpecker analysis and the KNF Conservation Plan (Johnson 2004a), all combined mine-transmission line alternatives would provide general forest species habitat with sufficient quality and quantity of the diverse age classes of vegetation needed for viable populations. ***In all combined mine-transmission line alternatives, sufficient general forest habitat would be available and the populations of species using that habitat would remain viable.***

State Requirements

Alternatives 3 and 4 would comply with the MMRA regarding disturbed lands being reclaimed to a post-mining land use with stability and utility comparable to that of the pre-mining landscape. Draft findings regarding compliance with MFSA requirements are discussed in the Summary, beginning on p. S-53.

3.25.4 Forest Service Sensitive Species

Sensitive species are administratively designated by the Regional Forester (Forest Service Manual (FSM) 2670.5) and are those species for which population viability is a concern. Conservation Assessments have been completed for some sensitive species to assist land managers with planning efforts. The KNF completed Conservation Plan to demonstrate forest-wide conservation of sensitive species and their habitat and help prevent sensitive species from being listed as threatened or endangered (Johnson 2004a).

3.25.4.1 Regulatory Framework

The Organic Administration Act authorizes the Forest Service to regulate the occupancy and use of National Forest System lands. The Forest Service's locatable minerals regulations are promulgated at 36 CFR 228, Subpart A. The regulations apply to operations conducted under the U.S. mining laws as they affect surface resources on National Forest System lands under the jurisdiction of the Secretary of Agriculture. One of these regulations (36 CFR 228.8) requires that mining activity be conducted, where feasible, to minimize adverse environmental impacts on National Forest surface resources. 36 CFR 228.8 also requires that mining operators take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations.

The National Forest Management Act requires the Secretary of Agriculture to promulgate regulations specifying guidelines for land management plans that "provide for the diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet overall multiple-use objectives…" The "specific land area" (scale) for providing diversity is established in the framework as the area covered by the Forest Plan, or the entire KNF. One of the KFP goals is to "maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species… and in sufficient quality and quantity to maintain habitat diversity representative of existing conditions" (II-1 #7).

Sensitive species are designated by the Regional Forester (FSM 2670.5). FSM 2672.42 directs the Forest Service to conduct a biological evaluation (BE) to analyze impacts on sensitive species. The sensitive species analysis in this document meets the requirements for a BE as outlined in

FSM 2672.42. FSM 2670.22 requires that the Forest Service develop and implement management practices to ensure that sensitive species do not become threatened or endangered because of Forest Service actions and maintain viable populations of all native and desired nonnative wildlife, fish, and plant species in habitats distributed throughout their geographic range on National Forest System lands. Any decision on the Montanore Project cannot result in loss of sensitive species viability or create significant trends toward federal listing (FSM 2670.32). Sensitive plant species identified within the analysis area are listed in Table 214. State wildlife Species of Concern are discussed in section 3.25.7, *Other Species of Interest*.

3.25.4.2 Bald Eagle

3.25.4.2.1 Regulatory Framework

Federal Requirements

The bald eagle was removed from the federal threatened species list in 2007 (USFWS 2007b) and was subsequently added to the Forest Service sensitive species list. Bald eagles are also protected by two federal laws: the Bald and Golden Eagle Protection Act (Eagle Act) and the Migratory Bird Treaty Act (MBTA). The Eagle Act prohibits the “take, possession, sale, purchase, barter, offer to sell, purchase, or barter, transport, export, or import, of any bald or golden eagle, alive or dead, including any part, nest, or egg, unless allowed by permit.” “Take” is defined as “pursue, shoot, shoot at, poison, wound, kill, capture, trap, collect, molest, or disturb.” The term “disturb” is defined as “to agitate or bother a bald or golden eagle to a degree that causes, or is likely to cause, based on the best scientific information available, 1) injury to an eagle, 2) a decrease in its productivity, by substantially interfering with normal breeding, feeding, or sheltering behavior, or 3) nest abandonment, by substantially interfering with normal breeding, feeding, or sheltering behavior” (50 CFR 22).

Regulations under the Eagle Act (50 CFR 22) allow for the limited take of bald eagles, or their nests, when the take is associated with otherwise lawful activities and the take would be compatible with the preservation of the bald eagle (74 Federal Register 46835). Compatible with the preservation of the bald eagle means the actions would have to be consistent with the goal of stable or increasing populations. Under these regulations, the USFWS may issue take permits, based on regional population thresholds, to allow take that results in mortality of eagles or an eagle nest under special circumstances. The permits authorize limited, non-purposeful take of bald eagles and golden eagles; authorizing individuals, companies, government agencies (including tribal governments), and other organizations to disturb or otherwise take eagles in the course of conducting lawful activities such as operating mines. Most permits issued under the regulations authorize disturbance. In limited cases, a permit may authorize the physical take of eagles, but only if every precaution is taken to avoid physical take. Removal of an eagle nest is allowed only where it is necessary to alleviate a safety hazard to people or eagles, necessary to protect human health or safety, the nest prevents the use of a human-engineered structure, or the activity, or mitigation for the activity, will provide a net benefit to eagles (50 CFR 22.27).

Table 214. Sensitive Wildlife Species on the KNF and Status within the Montanore Project Analysis Area.

Sensitive Species	Status[1]	Determination[2]	Comments
American Peregrine Falcon (*Falco peregrinus anatum*)	NS	No Impact	May occur in the analysis area, but no suitable habitat would be affected by project alternatives. Species dropped from further analysis.
Bald Eagle (*Haliaeetus leucocephalus*)	K	May Impact	Species and suitable habitat observed in analysis area
Bighorn Sheep (*Ovus canadensis*)	NS	No Impact	No suitable habitat available in analysis area
Black-backed Woodpecker (*Picoides arcticus*)	S	May Impact	Observed outside, but in vicinity of analysis area and suitable habitat available
Coeur d'Alene Salamander (*Plethodon vandykei idahoensis*)	S	May Impact	Adverse effect not likely because species not observed in analysis area since 1989 and habitat in analysis area degraded
Common Loon (*Gavia immer*)	NS	No Impact	No suitable habitat available in analysis area
Fisher (*Martes pinnanti*)	K	May Impact	Species and suitable habitat observed in analysis area
Flammulated Owl (*Otus flammeolus*)	K	May Impact	Species and suitable habitat observed in analysis area
Gray Wolf (*Canus lupus*)	K	May Impact	Species and suitable habitat observed in analysis area
Harlequin Duck (*Histrionicus histrionicus*)	K	May Impact	Species and suitable habitat observed in analysis area
North American Wolverine (*Gulo gulo*)	K	May Impact	Species and suitable habitat observed in analysis area
Northern Bog Lemming (*Synaptomys borealis*)	NS	No Impact	Analysis area not within species range
Northern Leopard Frog (*Rana pipiens*)	NS	No Impact	No suitable habitat available in analysis area
Townsend's Big-eared Bat (*Corynorhinus townsendii*)	K	May Impact	Species and suitable habitat observed in analysis area
Western Toad (*Bufo boreas*)	K	May Impact	Species and suitable habitat observed in analysis area

[1] Status Key:
K = Species is known to occur within the analysis area.
S = Species is suspected to occur within analysis area.
NS = Species is not suspected to occur within the analysis area, and is dropped from further evaluation.
[2] Determination Key:
No Impact = Species is not suspected to occur within the analysis area.
May Impact = May impact individuals or their habitat but will not likely contribute to a trend toward federal listing or cause a loss of viability to the population or species.
Source: USDA Forest Service 2011f; Westech 2005a; MNHP 2014; and KNF data for District observation and historical records (NRIS Wildlife).

The MBTA specifically protects migratory bird nests from possession, sale, purchase, barter, transport, import, and export, and take. The other prohibitions of the MBTA, capture, pursue, hunt, and kill, are inapplicable to nests. The regulatory definition of take, as defined by 50 CFR 10.12, means to pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt hunt, shoot, wound, kill, trap, capture, or collect. Executive Order 13186, Responsibilities of Federal agencies to Protect Migratory Birds, requires analysis of effects of federal actions on migratory birds as part of the environmental analysis process. In 2008, the USDA Forest Service and USFWS signed an MOU outlining the responsibilities of both parties in implementing the Executive Order. Under the MOU, the Forest Service will, during the NEPA process, evaluate the effects of agency actions on migratory birds, focusing first on species of management concern along with their priority habitats and key risk factors.

State Requirements

The State of Montana also has regulations in place to protect bald eagles. The intent of the Nongame and Endangered Species Act (87-5-103, MCA) is to "provide adequate remedies for the protection of the environmental life support system from degradation and provide adequate remedies to prevent unreasonable depletion and degradation of natural resources." This Act has similar language to the MBTA.

3.25.4.2.2 Analysis Area and Methods

Analysis Area

The analysis area for direct, indirect, and cumulative impacts to individuals and their habitat are all lands along US 2 from the Sedlak Park Substation to the Libby Loadout and within 1 mile of the transmission line alignment that are within the Bald Eagle Consultation Area (USFWS 2001). The 1-mile buffer adjacent to the transmission line alignments is based on the impact assessment requirements for linear features under MFSA (DEQ 2004). The analysis area occurs in the Crazy, Silverfish, McSwede, McElk and Riverview PSUs. This area includes the Sedlak Park Substation and loop line. The analysis area for assessing trend toward federal listing and population viability is the KNF.

Methods

The National Bald Eagle Management Guidelines (NBEMG) (USFWS 2007c) provide recommendations for avoiding disturbance to bald eagles, and also encourage the continued development and use of state-specific management plans. The Montana Bald Eagle Management Plan (MBEMP) (Montana Bald Eagle Working Group 1994) and the 2010 addendum developed by the Montana Bald Eagle Working Group (Montana Bald Eagle Working Group 2010) stated that the Plan "will also serve as the conservation and management plan when bald eagles are delisted." The MBEMP and addendum provides guidance for bald eagle habitat management on the KNF. The effect of any proposed activity on potential eagle habitat (½ mile of major water source) and any known eagle nests located within the bald eagle habitat will be discussed in relation to the 2010 Montana Bald Eagle Management Guidelines in lieu of the NBEMG. The NBEMG are more appropriate for states such as Florida, which have higher concentrations of bald eagles and have built nests near pre-existing human activity whereas Montana bald eagles are likely more accustomed to areas with less human activity and rural areas.

Eagle population ecology, biology, habitat description, and relationships identified by research are described in Montana Bald Eagle Working Group (MBEWG) (1991, 1994, 2010); USFWS (1995b, 1999); and USFWS (2007b). Eagle occurrence data come from recent District wildlife observation records, Forest historical data (NRIS Wildlife), and KNF monitoring data (USDA Forest Service 2008c). Nesting attempts on the KNF have increased significantly over the last two decades. Only one active nest was known to occur in 1978, whereas 35 active nests (15 on National Forest System lands and 20 on private land) were known and monitored in 2008. Nest success for active nests in 2008 was 41 fledglings. This is above the 20-year average of 24.5 fledges calculated for the last KNF monitoring reporting period (1988-2007, USDA Forest Service 2008c)

MBEMP guidelines identify four general areas of management concerns for bald eagles: nest sites, concentrated foraging areas winter communal roost sites, and mortality risks. In addition, the MBEMP describes seasonal restrictions and buffers around nests, foraging, and winter roost sites, based on activity type, to minimize disturbance to (MBEWG 2010). Buffers consist of visual buffers based on whether the human activity is visible from the nest, and distance buffers determined by the type of activity. MBEWG (2010) recommends seasonal restrictions from February 15 through August 15 for the following activities:

- Construction and maintenance including buildings roads, trails, or any other outside construction within direct line of sight of an active nest.
- Loud noises including fireworks, blasting, and operation of forest harvest machinery (skidders, trucks, chainsaws, etc.), jackhammers, construction equipment, etc.
- Forest management activities, thinning, and fuels reduction including all activities associated with the removal forest vegetation around occupied nests.
- Concentrated recreation including, but not limited to, hiking, bird-watching, fishing (on and offshore), hunting, boating and use of personal watercraft.

Foraging areas, especially in the winter, often are found along highway and railroad corridors where animals killed by vehicles or trains occur. Winter habitat is generally dictated by the presence and abundance of food, open water, and secure night roost sites (MBEWG 1994). Effects indicators will be a quantitative (acres affected) or qualitative (potential to increase risk of mortality) effects analysis for the four habitat categories/management concerns. The impacts analysis includes an evaluation of the mitigation measures proposed by MMC or the agencies described in sections 2.4.6.3, *Grizzly Bear* and 2.9.6, *Wildlife Mitigation Measures*, recommendations outlined in Suggested Practices for Avian Protection on Power Lines (APLIC 2006) and Reducing Avian Collisions with Power Lines (APLIC 2012), and measures described in MMC's proposed Environmental Specifications (MMI 2005b) and the agencies' Environmental Specifications (Appendix D).

3.25.4.2.3 Affected Environment

Bald eagles occur as both seasonal migrants and year-round residents within the boundaries of the KNF. Based on the bald eagle habitat area boundaries agreed to by the USFWS (USFWS 2001), about 564,558 acres (242,965 acres National Forest System land, 275,470 acres private land, and 46,123 acres open water) of potential bald eagle habitat occurs in the KNF (USFWS 2001). Nesting on the KNF has increased significantly over the last 2 decades. Only one active nest was known to occur in 1978, whereas 35 active nests (15 on National Forest System lands and 20 on private land) were known and monitored in 2008. Nest success for active nests in 2008 was 41 fledglings. This is above the 20 year average of 24.5 fledges calculated for the last KNF monitoring reporting period (1988-2007, USDA Forest Service 2008c).

Three known eagle nests are within the analysis area (Figure 91). In 2006, a pair of bald eagles initiated nesting at a site, known as the Silverfish nest, located along the Fisher River just north of Silver Butte Road and just west of US 2 in the Silverfish PSU, about 600 feet west of MMC's proposed transmission line alignment Alternative B. Another active nest site is located along the Fisher River on private land about 1.4 miles north of the proposed transmission line. A third active nest is along Libby Creek about a mile south of the Libby Loadout and east of US 2. Bald eagles tend to use the same breeding area, and often the same nest, each year (MBEWG 1994) and these nests are likely to be active in the future.

Several bald eagle foraging, perching, and roosting areas are located along the Fisher River. Bald eagle foraging is occasionally observed along US 2 and in the major drainages in the Silverfish PSU (Bratkovich, pers. comm. 2006). In the fall, eagle use of Libby Creek is usually limited to about 8 miles upstream of its confluence with the Kootenai River.

Wintering bald eagle numbers have fluctuated over the years depending on food sources (fish from open waters and dead animals along roads and railroad tracks) and winter conditions (open versus frozen water for foraging habitat). Mid-winter bald eagle counts have averaged 88 bald eagles over the past 25 years (1989-2013, KNF bald eagle monitoring records). Winter use within the analysis area occurs along the US 2 corridor.

3.25.4.2.4 Environmental Consequences

Alternative 1 – No Mine

Alternative 1 would not directly or indirectly affect bald eagle nesting, foraging, communal roost, or other potential habitat. Without the proposed mine, traffic on US 2 from White Haven to Bear Creek Road would grow at an annual rate of 1.2 percent, increasing from a predicted 1,914 vehicles per day in 2010 to 2,401 vehicles in 2029. The traffic on Bear Creek Road averaged 16,338 vehicles per year between 1986 and 1991. Assuming traffic on the Bear Creek Road increased at the same rate as traffic on US 2, average traffic would be 20,493 vehicles per year in 2010. Without the proposed mine, traffic would grow at an annual rate of 1.2 percent increasing to 25,707 vehicles per year in 2029. No improvements would be completed to Bear Creek Road under this alternative. The increase in traffic in Alternative 1 would slightly increase the risk of increased eagle mortality on the Bear Creek Road and US 2 in the Bald Eagle Consultation Area.

Alternative 2 – MMC's Proposed Mine

The proposed mine would generate a negligible increase in traffic during the Evaluation Phase and the Construction Phase between Libby and the intersection with the Libby Creek Road. The increase would have a negligible effect on eagle mortality risk in the Bald Eagle Consultation Area. After the Bear Creek Road was reconstructed, traffic volume would increase, with an additional 132 vehicles per day on US 2, including 52 trucks and six buses. The increase in traffic would be 5 to 7 percent. Eagles are vulnerable to oncoming high-speed traffic, especially when gorged, ambient temperatures are well below freezing and wind is calm (MBEWG 1994). The increase in US 2 traffic in Alternative 2 during operations would slightly increase the risk of increased eagle mortality on US 2 in the Bald Eagle Consultation Area.

Traffic would increase substantially on the Bear Creek Road, a short (less than 1 mile) segment of which is in the Bald Eagle Consultation Area. Estimates of increased annual traffic volume range from 187 percent to 234 percent (Table 172 in the *Transportation* section). The increase in U.S. traffic in Alternative 2 would substantially increase the risk of increased eagle mortality on the short segment of the Bear Creek Road that is in the Bald Eagle Consultation Area. When the mill ceased operations in the Closure Phase, mine traffic volume would be substantially less than shown in Table 172. Future traffic volume when all activities at the mine are completed in the Post-Closure Phase would be higher than in Alternative 1 because of reconstruction of Bear Creek Road and loss of the Little Cherry Loop Road beneath the impoundment. Mortality risk to the bald eagle would decrease on the Bear Creek Road compared to operations, but the permanently improved road conditions (increased road width, improved sight distance, paving) and higher traffic speeds would result in a permanently higher bald eagle mortality risk the compared to pre-mine conditions.

Alternative 3 – Agency Mitigated Poorman Impoundment Alternative and Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Alternatives 3 and 4 would have similar effects on traffic volume on the Bear Creek Road and US 2 as Alternative 2. Creation of a supply staging area in Libby and consolidating shipments to the mine area would slightly reduce traffic and associated eagle mortality risk from that estimated for Alternative 2.

Alternative A – No Transmission Line

Alternative A would not directly or indirectly impact bald eagle nesting, foraging, communal roost, or other potential habitat. The increase in traffic in Alternative A would slightly increase the risk of increased eagle mortality on US 2 in the Bald Eagle Consultation Area.

Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

About 0.5 mile of MMC's Proposed Transmission Line would have direct impacts on about 9 acres of bald eagle habitat in the nesting zone (Table 215). Alternative B would also temporarily disturb 33 acres of home range foraging area for nesting bald eagles, and 103 acres of other potential bald eagle habitat during transmission line construction. The clearing area for Alternative B would include 4 acres of old growth habitat on private land along the Fisher River and a short stretch of Miller Creek. Alternative B would likely result in the clearing of large spruce and cottonwood trees in these old growth areas that provide potential bald eagle nest sites. The clearing area associated with Alternative B would be within both the visual and distance buffers of an existing nest site. Bald eagles often avoid areas of high human use for nesting, foraging, perching, and roosting; they have shown a wide range of sensitivity to human disturbance (Stalmaster and Newman 1978; Knight and Knight 1984; Martell 1992; Beuhler *et al.* 1991; McCarigal *et al.* 1991). In addition to physical losses of habitat, impacts on bald eagles from Alternative B may include disturbance of breeding bald eagles and nest abandonment due to increased noise and the presence of humans and machinery and would likely require a federal take permit under the Eagle Act. Temporary disturbance impacts from Alternative B may also occur if increased noise and human presence associated with construction, including construction of the Sedlak Park Substation and loop line, caused eagles to avoid foraging in some areas.

Table 215. Transmission Line Impacts on Bald Eagle Nesting Habitat and Potential Bald Eagle Habitat by Transmission Line Alternative.

Transmission Line Alternative	Nearest Distance to Nest Site (miles)	Nest Site Area (Visual Buffer)[1] (acres)	Primary Use Area (Distance Buffer)[2] (acres)	Home Range Foraging Area[3] (acres)	Other Potential Bald Eagle Habitat[4] (acres)
B-North Miller Creek	0.07	9	10	33	103
C-Modified North Miller Creek	0.58	0	0	13	107
D-Miller Creek	0.58	0	0	13	107
E-West Fisher Creek	0.58	0	0	26	112

The transmission line disturbance area includes typical tree clearing width of 150 feet for Alternative B and 200 feet for Alternatives C-R, D-R, and E-R; and the disturbance area for the Sedlak Park Substation and access road. Areas of impact overlap between zones are not counted.
[1] Visual buffer = The initial buffer implemented based on whether the human activity is visible from within 0.25 mile radius of nest site.
[2] Distance Buffer = In the absence of adequate visual buffers, a distance buffer from 0.25 to 0.5 mile radius of nest site determined by the type of activity.
[3] Foraging Area (formally Zone 3) = suitable foraging habitat within 2.5 miles of nest site. Foraging habitat consists of rivers, streams, and wetland areas.
[4] Other potential bald eagle habitat = all lands within the analysis area.
Source: GIS analysis by ERO Resources Corp. using KNF data.

The likelihood of the 230-kV transmission line resulting in the electrocution of bald eagles or other raptors is extremely low; electrocution of raptors is primarily a problem associated with lower-voltage distribution lines (APLIC 2006). Also, electrocutions potentially caused by the transmission line would be minimized through implementation of recommendations outlined in APLIC (2006), which are based on a minimum spacing of 60 inches between phases or between phase and ground wires. The transmission line from BPA's loop line would not pose a risk of electrocution of raptors because phase spacing would be a minimum of 20 feet.

Although raptors are generally less vulnerable to collisions with power lines than other bird species (Olendorff and Lehman 1986), the proximity of the Alternative B transmission line, including BPA's Substation and loop line, to nesting bald eagles and their foraging habitat along the Fisher River would add to the risk of bald eagle collisions with the transmission line. Potential collisions of bald eagles with the transmission line would be reduced by constructing the transmission line according to recommendations outlined in APLIC (2012). Applicable recommendations outlined in APLIC include locating the transmission line away from streams and other potential flight corridors, placement of the lines below treeline or other topographical features, and installation of line-marking devices. MMC indicated no aviation flight paths were identified for the preferred corridor and no markers or other warning devices were planned (MMI 2005b).

MMC did not propose any timing restrictions for winter-time transmission line construction. Winter-time transmission line construction would slightly increase traffic on US 2 in the analysis area and would slightly increase eagle mortality risk.

Alternative C-R – Modified North Miller Creek Transmission Line Alternative

Alternative C-R would have no direct physical impacts on bald eagle habitat in the nesting zone. About 13 acres of bald eagle foraging habitat and 107 acres of other potential habitat would be temporarily disturbed during construction of Alternative C-R (Table 215). The clearing area for

Alternative C-R would not include any old growth habitat on private land along the Fisher River. Temporary disturbance impacts from Alternative C-R may also occur if increased noise and human presence associated with construction, including construction of the Sedlak Park Substation and loop line, caused eagles to avoid foraging in some areas. These impacts are likely to be minor, given the availability of foraging habitat in the surrounding area.

The location of the Alternative C-R transmission line alignment on an east-facing ridge immediately north of the Sedlak Park Substation would reduce the risks of bald eagle wire strikes and electrocutions relative to Alternative B. Similar to Alternative B, recommendations outlined in Suggested Practices for Avian Protection on Power Lines (APLIC 2006) and Reducing Avian Collisions with Power Lines (APLIC 2012) would be implemented.

Section 2.9.6.2.1, *Bald Eagle* describes the agencies' mitigation for the bald eagle. MMC would either: 1) not clear vegetation or conduct other construction activities during the breeding season (February 1 to August 15) in potential bald eagle nesting habitat or; 2) fund or conduct field and/or aerial reconnaissance surveys to locate any new bald eagle or osprey nests along specific segments of the transmission line corridor in Alternatives C-R, D-R, and E-R. Surveys would be conducted between March 15 and April 30, one nesting season immediately before transmission line construction. If an active nest were found, guidelines from the Montana Bald Eagle Management Plan (Montana Bald Eagle Working Group 2010) would be followed to provide management guidance for the immediate nest site area (Zone 1), the primary use area (Zone 2), and the home range area (Zone 3) as long as they were in effect. This mitigation would minimize affecting a bald eagle nest.

The agencies' mitigation also includes other timing restrictions. All activities for both transmission line construction seasons and during decommissioning of the transmission line on National Forest System and State trust lands located within the CYRZ and Cabinet Face BORZ would occur between June 16 and October 14. No transmission line construction in elk, white-tailed deer, or moose winter range between December 1 and April 30 unless approved by the agencies. The agencies' timing restrictions would minimize any increase in traffic on US 2 in the analysis area and increased eagle mortality risk.

The agencies' Environmental Specifications (Appendix D) include additional monitoring and mitigation not described in MMC's Environmental Specifications. As described in Appendix D, areas of high risk for bird collisions where line-marking devices may be needed, such as the Fisher River crossing, and recommendations for type of marking device would be identified through a study conducted by a qualified biologist and funded by MMC.

Alternative D-R – Miller Creek Transmission Line Alternative

The impacts on bald eagles from Alternative D-R would be the same as Alternative C-R. Modifications to the transmission line alignment and mitigation described in Alternative C-R would be implemented in Alternative D-R.

Alternative E-R – West Fisher Creek Transmission Line Alternative

Alternative E-R would have no direct physical impacts on bald eagle habitat in the nesting zone. About 26 acres of bald eagle foraging habitat and 112 acres of other potential habitat would be temporarily disturbed during construction of Alternative E-R (Table 215). The clearing area for Alternative E-R would include about 7 acres of old growth habitat on private and State land where the transmission line crossed the Fisher River and paralleled West Fisher Creek.

Alternative E-R would likely result in the clearing of large spruce and cottonwood trees in these old growth areas that provide potential bald eagle nest sites. Temporary disturbance impacts from Alternative E-R may also occur if increased noise and human presence associated with construction, including construction of the Sedlak Park Substation and loop line, caused eagles to avoid foraging in some areas. These impacts are likely to be minor, given the availability of foraging habitat in the surrounding area. The risks of bald eagle wire strikes and electrocutions would be the same as Alternatives C-R and D-R. Modifications to the transmission line alignment and mitigation described in Alternative C-R would be implemented in Alternative E-R.

Cumulative Effects

Past actions (Appendix E) applicable to cumulative effects on bald eagle include existing road and associated traffic volume, primarily on US 2, and existing roads and human disturbance in the analysis area. Future actions that may increase traffic volume on US 2, and human disturbance in the analysis area include private land development, the Miller-West Fisher Vegetation Management Project, the Coyote Improvement Vegetation Management Project, the Silverbutte Bugs timber sale and the Flower Creek Vegetation Management Project. If timber harvest activities occurred concurrently with mine or transmission line construction and operations, higher traffic volume and associated increased eagle mortality risk along US 2 may occur. No other past, current, or reasonably foreseeable actions are anticipated to contribute to cumulative impacts on bald eagles.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8. In these alternatives, MMC did not propose to implement feasible measures to minimize effects on the bald eagle or practicable measures to maintain and protect wildlife habitat. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would incorporate feasible and practicable measures to minimize adverse environmental impacts on the bald eagle and wildlife habitat. These measures would include realigning the transmission line away from an active eagle nest, limiting winter-time transmission line construction, either not clearing vegetation or conducting construction activities during breeding season in bald eagle habitat, or fund or conduct surveys to locate active nests in appropriate habitat, creating a supply staging area in Libby and consolidating shipments to the mine area to reduce traffic, and assessing areas of high risk for bird collisions where line-marking devices may be needed. Transmission Line Alternatives C-R and D-R would avoid old growth habitat on private land along the Fisher River.

National Forest Management Act/Kootenai Forest Plan

p.II-1 #6 – *Determine the status of sensitive species and provide for their environmental needs as necessary to prevent them from becoming threatened or endangered:* Bald eagle habitat and nest sites occur with analysis area between and NFS road #278 (Bear Creek Road) to the Libby Loadout near Libby and along the Fisher River. In Mine Alternative 2 and Transmission Line Alternative B, MMC did not propose to implement all feasible measures to minimize effects on the bald eagle. The agencies' alternatives would include measures to minimize effect on the bald eagle. All alternatives may affect individual bald eagles and their habitat within the analysis area, but would not contribute to a trend toward federal listing or cause a loss of viability to the population or species.

p.II-1 #7 – *Maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species:* All action alternatives would maintain diverse age classes for viable populations of the bald eagle. Transmission Line Alternatives C-R and D-R would avoid old growth habitat on private land along the Fisher River.

p.II-22, 23 – *Maintenance of viable populations of existing native and desirable non-native vertebrate species, as monitored through indicator species, attained through the maintenance of a diversity of plant communities and habitats:* See p.II-1 #7 above for habitat diversity. Bald eagles are monitored as an indicator species for river and lake habitats. Their occurrence and estimate of population is monitored through District observations and FWP reports.

p.II-23 – *Best Management Practices, as specified by the MBEWG (updated by the MBEWG in 2010) will be applied to all known bald eagle nest sites, important roost or perch sites, and know wintering foraging sites:* Alternative B would not comply with this direction. In Alternative B, MMC did not propose to implement all feasible measures to minimize effects on the bald eagle, such as avoiding the nest along the Fisher River. All other alternatives would include BMPs or avoidance to minimize effect on known bald eagle nest sites, important roost or perch sites, and know wintering foraging sites.

Forest Service Sensitive Species Statement of Findings

The no action alternatives would not impact individual bald eagles or their habitat within the analysis area, and would not contribute to a trend toward federal listing or cause a loss of viability to the population or species. ***All action alternatives may impact individual bald eagles and their habitat within the analysis area, but would not contribute to a trend toward federal listing or cause a loss of viability to the population or species.*** All action alternatives may affect the bald eagle and their habitat by increasing mortality risks in winter foraging area. All action transmission line alternatives would disturb home range foraging areas and may displace eagles from foraging areas during transmission line construction. The USFWS has removed the bald eagle from federal listing. Nesting on the KNF has increased significantly over the last 2 decades.

Bald and Golden Eagle Protection Act

Alternative B would not comply with the Eagle Act, as it would likely require obtaining a federal eagle take permit for which MMC has not applied. The agencies' transmission line alternatives would result in minimal impacts on individual bald eagles or eagle populations and habitat, and would comply with the Eagle Act.

Migratory Bird Treaty Act and Executive Order 13186

All action alternatives would comply with the MBTA, Executive Order 13186, and its associated MOU by evaluating the effects of federal actions on migratory birds as part of the NEPA process and promoting conservation of and minimizing adverse impacts on migratory birds.

State Requirements

Alternatives 3 and 4 would comply with the MMRA regarding disturbed lands being reclaimed to a post-mining land use with stability and utility comparable to that of the pre-mining landscape.

Draft findings regarding compliance with MFSA requirements are discussed in the Summary, beginning on p. S-53. All alternatives would comply with the Nongame and Endangered Species Act.

3.25.4.3 Black-backed Woodpecker

3.25.4.3.1 Analysis Area and Methods

Black-backed woodpecker population ecology, biology, habitat description, and relationships identified by research are described in Samson (2006a, 2006b), O'Connor and Hillis (2001), Dixon and Saab (2000), Powell (2000), Cherry (1997) and Hutto (1995).These provided guidance in evaluating habitat and potential effects to black-backed woodpeckers, and are incorporated by reference. Black-backed woodpecker occurrence data come from recent District wildlife observation records and KNF historical data (NRIS Wildlife).

Other than NFMA and KFP direction previously described for sensitive species, there is no federal management direction specific to black-backed woodpeckers. Bonn *et al*. (2007) provides some Regional guidance for conducting project-level analysis to determine effects to black-backed woodpeckers. Black-backed woodpecker habitat was analyzed using GIS layers on fire and timber harvest history, stand type, and stand age/size. Additional sources used for analysis includes snag data, prescribed burn records for the analysis area, and Regional fire history summaries (Northern Rockies Coordination Center 2004-2011).

High quality habitat is defined as areas where recent (less than 8 years old) mixed-lethal or stand-replacement fires have occurred. Black-backed woodpeckers have been found to be almost entirely restricted to early post-fire forests (Hutto 1995). General forest (low quality) habitat consists of forested areas with patches of snags produced by insect and disease. Specific black-backed woodpecker habitat information was not available for private or state-owned lands in the analysis area, much of which has been logged in the past 20 to 30 years.

Indicators for comparing alternative effects on black-backed woodpecker included changes in high-quality and general forest habitat.

The analysis area for black-backed woodpeckers is described in section 3.25.1, *Introduction.* The analysis area for determination of population trend and contribution toward population viability is the KNF.

3.25.4.3.2 Affected Environment

Habitat for black-backed woodpeckers consists of boreal and montane forest where wood-boring beetle (Cerambycidae and Buprestidae) and bark beetle (Dendroctus spp.) outbreaks are occurring as a result of disturbances caused by fire, wind, and disease.

Research conducted in Montana (Hutto 1995; Caton 1996; Hitchcox 1996; Hejl and McFadzen 2000; Powell 2000) strongly suggests black-backed woodpeckers require fire-killed trees for long-term survival. High quality black-backed woodpecker habitat is defined as recent (≤8 years old) mixed-lethal or stand-replacement fire areas where an abundance of snags are available. Fire-created black-backed woodpecker habitat provides the best conditions for 2 to 3 years following the fire then begins to decline as tree moisture content decreases and wood borer larvae decline (Bonn *et al*. 2007). Fire-killed trees generally do not provide insect food sources beyond 5 to 7 years (Caton1996; Murphy and Lehnhausen 1998); however, secondary mortality from fire and insect attacks often extend the availability of quality habitat. Hoyt and Hannon (2002) documented black-backed woodpecker use of fire areas up to 8 years after a fire occurred.

The analysis area has no high quality habitat because there have been no fires during the past 8 years. Low quality black-backed woodpecker habitat in the Crazy, Silverfish, McElk, and Riverview PSUs consists of general forest habitat that supports populations of resident black-backed woodpeckers. Based on potential habitat data, about 15,143 acres of general forest habitat is in the Crazy PSU, while 15,437 acres of general forest habitat is in the Silverfish PSU.

As primary cavity-nesters, black-backed woodpeckers require dead or live trees with heartwood rot and show a preference for Douglas-fir, ponderosa pine, lodgepole pine, and western larch. According to Thomas (1979), a PPL of 40 percent or more should maintain viable populations of birds dependent on cavities for nest sites. The existing PPL for the Crazy and Silverfish PSUs is 73 and 90 percent, respectively.

On a forest-wide level, potential black-backed woodpecker habitat is abundant, broadly distributed, and totals 1,317,790 acres of general forest habitat. Across the KNF, wildfires over the last 8 years ranged from 11 to 4,723 acres per year and created a total of about 9,390 acres of high quality habitat (Northern Rockies Coordination Center 2004-2011).

The nearest recorded observation of a black-backed woodpecker to the analysis area occurred in 1995 in a burned area west of Rock Creek (MNHP 2014). No black-backed woodpeckers were observed during black-backed woodpecker surveys of more than 1 mile of the Libby Creek wildfire burn area in 2003 and 2004 (see Project record). No black-backed woodpeckers were observed during breeding bird monitoring and point count surveys of old growth stands in and adjacent to the proposed impoundment sites and Libby Plant Site conducted in 1992 (Mitchell and Bratkovich 1993), 2002, and 2004 (see Project record). Similarly, no black-backed woodpeckers have been observed during Region One (Forest Service) landbird monitoring surveys of transects established directly northwest of the proposed LAD Area 1 and in Miller Creek along NFS road #4724 in 1994, 1995, 1996, 1998, 2000, 2002, and 2004 (Ibid). The majority of the private and State lands in the analysis area has high road densities, allowing access for firewood collection, and has been logged in the past 20 to 30 years, and it is not likely that snags have been left standing. As a result, snag and down wood important to black-backed woodpeckers is likely to be less available on private and State lands.

Across the Forest Service Northern Region, the black-backed woodpecker is considered secure in terms of persistence (Samson 2006a, 2006b). The Northern Region Black-backed Woodpecker Overview (Bonn *et al*. 2007) shows region-wide populations are increasing. High quality habitat is also on the rise due to large wildfire activity since 2000.

3.25.4.3.3 Environmental Consequences

Activities associated with mine and transmission line construction and operation have the potential to impact black-backed woodpecker habitat. Impacts from the mine (Table 216) and transmission line alternatives (Table 217) are described in the following subsections. None of the proposed alternatives for the mine or the transmission line will impact high-quality black-backed woodpecker habitat (recently burned forest).

Alternative 1 – No Mine

The No Mine Alternative would not have any direct, indirect, or cumulative impacts on black-backed woodpeckers or their habitat. Over time, with continued fire suppression and lack of active forest management, indirect effects of this alternative would include a continued trend toward later successional habitats.

Alternative 2 – MMC's Proposed Mine

Alternative 2 would have no effect on black-backed woodpecker habitat in the Silverfish PSU. In the Crazy PSU, 889 acres of general forest habitat would be impacted (Table 216). The Alternative 2 tailings impoundment would result in the loss of 715 acres of general forest habitat in one localized area, which could displace one or more nesting black-backed woodpecker pairs that may have traditionally used the area.

Table 216. Impacts on Black-backed Woodpecker Habitat in the Analysis Area by Mine Alternative.

Habitat Type	[1] No Mine/Existing Conditions	[2] MMC's Proposed Mine	[3] Agency Mitigated Poorman Impoundment	[4] Agency Mitigated Little Cherry Creek Impoundment
General Forest Habitat (acres/%)	15,143	14,254 (889/6%)	14,425 (718/5%)	14,478 (665/4%)

Number in parentheses is the reduction in habitat acres/percent in habitat area compared to existing conditions.
Source: GIS analysis by KNF using KNF data.

Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Direct and indirect impacts from Alternative 3 on black-backed woodpecker would be slightly less than Alternative 2. In the Crazy PSU, Alternative 3 would affect 718 acres of general forest foraging habitat (Table 216). The Alternative 3 tailings impoundment would result in the loss of 627 acres of habitat in one localized area, which could displace one or more nesting black-backed woodpecker pairs that may have traditionally used the area.

Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Direct and indirect impacts from Alternative 4 on black-backed woodpecker would be less than Alternative 2. In the Crazy PSU, Alternative 4 would affect 665 acres of general forest habitat (Table 216). The Alternative 4 tailings impoundment would result in the loss of 571 acres of mapped habitat in one localized area, which could displace one or more nesting black-backed woodpecker pairs that may have traditionally used the area.

Alternative A – No Transmission Line

The No Transmission Line Alternative would have no direct or indirect impacts on black-backed woodpecker habitat. The effects would be the same as Alternative 1.

Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

Alternative B would affect 35 acres of general forest habitat in the Crazy PSU, and 28 acres of general forest habitat in the Silverfish PSU (Table 217). The Alternative B clearing area would include 15 acres of potential black-backed woodpecker habitat on State and private land outside of the Crazy and Silverfish PSUs. The quality of the black-backed woodpecker habitat on private land is unknown. Based on the lack of suitable habitat and black-backed woodpecker sightings, construction of the Sedlak Park Substation and loop line would not affect black-backed woodpeckers in any transmission line alternative.

Alternative C-R – Modified North Miller Creek Transmission Line Alternative

Impacts on black-backed woodpecker from Alternative C-R would be similar to Alternative B (Table 217), affecting 2 additional acres of general forest habitat in the Crazy PSU, 6 additional acres of general forest habitat in the Silverfish PSU, and 13 more acres of potential habitat on State and private land. The quality of the black-backed woodpecker habitat on private land is unknown. Impacts on general forest foraging habitat in the agencies' alternatives would be minimized through implementation of the agencies' Environmental Specifications (Appendix D) and a Vegetation Removal and Disposition Plan.

Alternative D-R – Miller Creek Transmission Line Alternative

Alternative D-R would affect 39 acres of general forest habitat in the Crazy PSU, and 82 acres of general forest habitat in the Silverfish PSU (Table 217). The Alternative D-R clearing area would include about 31 acres of coniferous forest providing potential black-backed woodpecker habitat on State and private land. The quality of the black-backed woodpecker habitat on private land is unknown.

Alternative E-R – West Fisher Creek Transmission Line Alternative

Effects of Alternative E-R would be similar to Alternative D-R (Table 217).

Table 217. Impacts on Black-backed Woodpecker Habitat in the Analysis Area by Transmission Line Alternative.

Habitat Type	[A] No Transmission Line	[B] North Miller Creek	[C-R] Modified North Miller Creek	[D-R] Miller Creek	[E-R] West Fisher Creek
Crazy PSU					
General Forest Habitat (acres/%)	15,143	15,108 (35/<1%)	15,108 (35/<1%)	15,104 (39/<1%)	15,104 (39/<1%)
Silverfish PSU					
General Forest Habitat (acres/%)	15,437	15,409 (28/<1%)	15,388 (49/<1%)	15,353 (82/<1%)	15,358 (79/<1%)
State and Private Land					
General Forest Habitat (acres)	NA	15	28	28	31

NA = Not applicable.
Numbers in parentheses is the reduction in habitat acres/percent in habitat area compared to existing conditions.
Source: GIS analysis by KNF using KNF data.

Combined Mine-Transmission Line Effects

Combined mine-transmission line impacts on black-backed woodpecker habitat in the analysis area are shown in Table 218. Impacts on black-backed woodpecker in the Crazy PSU would range from 700 to 922 acres of general forest foraging habitat. For all combined action alternatives, impacts on black-backed woodpecker in the Silverfish PSU would be due entirely to the transmission line. Impacts in the Silverfish PSU would range from 28 to 82 acres of potential general forest foraging habitat. Impacts on potential black-backed woodpecker habitat on State and private lands would be 59 acres for Alternative B, 47 acres for Alternatives 3C-R and 3D-R, 50 acres for Alternative 3E-R, 72 acres for Alternatives 4C-R and 4D-R, and 75 acres for Alternative 4E-R. The quality of the black-backed woodpecker habitat on private land is unknown. Based on the lack of suitable habitat and black-backed woodpecker sightings, construction of the Sedlak Park Substation and loop line would not affect black-backed woodpeckers with any alternative.

The loss of potential habitat resulting from the combined action alternatives could reduce the quality of the habitat in these PSUs for nesting black-backed woodpeckers through increased habitat fragmentation, edge effects, and disturbance effects. For all alternatives, construction of the tailings impoundment would result in the loss of between 571 and 715 acres of potential habitat in one localized area, which could displace one or more nesting black-backed woodpecker pairs that may have traditionally used the area. None of the alternatives would affect burned forest habitat or areas of bark-beetle outbreak preferred by black-backed woodpeckers. Despite several surveys conducted in the Crazy and Silverfish PSUs, no black-backed woodpecker nests were identified in the analysis area.

Cumulative Effects

The Affected Environment/Existing Condition describes the existing suitable habitat within the analysis area, primarily general forest habitat as no wildfires have occurred within the analysis area in recent years (≤8 years). In addition, adjacent planning areas were evaluated for potential impacts to high-quality habitat related to areas of disturbance that occur across project boundaries. There are no apparent conditions within proximity of the analysis area that would contribute to effects to black-backed woodpeckers.

Past Actions

The primary measure of habitat suitability is changes to nesting and foraging habitat, primarily changes to high quality habitat that developed as a result of wildfire. Past actions, particularly timber harvest, road construction, fire suppression, and firewood gathering activities, have contributed to a reduction in potential black-backed woodpecker habitat (USDA Forest Service 2003b). Fire suppression since the early 1900s has resulted in fewer severe fires on the landscape and has affected the creation of high quality habitat for black-backed woodpeckers. Timber harvest has occurred in the analysis area since the 1950s. Harvests that targeted beetle infested stands and post-fire areas for salvage reduced natural disturbance areas targeted by the woodpecker. In addition, regeneration harvests would have had the most impact on general forest habitat. Detailed description of previous vegetation management activities are found in Appendix E. Since the 1990s, application of KFP standards has resulted in the retention of snags and protection of old growth and riparian habitats. Also, there has been more reliance on intermediate harvest that leaves more forest structure (including large old trees), snags, and downed wood. Applications of these standards and management trends results in maintenance of general forest habitat.

Table 218. Impacts on Black-backed Woodpecker Habitat in the Analysis Area by Combined Mine-Transmission Line Alternative.

Measurement Criteria	[1] Existing Condition	[2] MMC's Proposed Mine	[3] Agency Mitigated Poorman Impoundment Alternative			[4] Agency Mitigated Little Cherry Creek Impoundment Alternative		
	TL-A	TL-B	TL-C-R	TL-D-R	TL-E-R	TL-C-R	TL-D-R	TL-E-R

General Forest Foraging Habitat (acres/%)	15,437	15,409 (28/<1%)	15,388 (49/<1%)	15,355 (82/<1%)	15,358 (79/<1%)	15,388 (49/<1%)	15,355 (82/<1%)	15358 (79/<1%)
State and Private Land								
Potential habitat affected (acres)	NA	59	47	47	50	72	72	75

Number in parentheses is the reduction in habitat acres compared to existing conditions.
Source: GIS analysis by KNF using KNF data.

There are no recent burned areas to provide high-quality habitat however, snag habitat, which is above the minimum needed of 40 percent in both PSUs, would assist in perpetuating the species through time until new areas of wildfire occur on the landscape.

No Action

The No Action alternatives (Alternative 1 and Alternative A) would not contribute to cumulative impacts on the black-backed woodpecker.

Action Alternatives

Ongoing and Reasonably Foreseeable Actions

Reasonably foreseeable actions include those federal, state, or private activities that are ongoing or scheduled to occur within the next five years, independent of this federal action. Appendix E, identifies those current and foreseeable actions in the analysis area that were determined to be appropriate for inclusion in the analysis of environmental effects.

Vegetation Management

The Miller-West Fisher Vegetation Management Project would include intermediate harvest of 1,206 acres, regeneration harvest of about 692 acres, precommercial thinning of 351 acres, and prescribed burning of 2,830 acres of National Forest System lands in the Silverfish PSU. The Coyote Improvement Vegetation Management Project is in the planning stages and would take place within the Crazy PSU. The project would harvest 240 acres to increase stand resiliency to mountain pine beetles. Silverbutte Bugs timber sale is in the Silverfish PSU and would be a small project like Coyote. Timber harvest and other clearing activities planned for the projects will contribute to cumulative losses of snags important to black-backed woodpecker. Activities associated with the projects are expected to retain cavity habitat within KFP-recommended levels for the Silverfish and Crazy PSUs. Also, while treatments associated with the projects will consume some snags and down wood, they also will create snags and down wood by killing live trees. Snags and down wood created in burned areas would provide both feeding and nesting habitat for the black-backed woodpecker.

Flower Creek timber sale is in the Treasure PSU and only has minimal overlap with the project with a small amount of the access road for Montanore located within this PSU. Flower Creek timber sale, like the timber sales mentioned above, would contribute openings or open-canopied habitat as well. Approximately 900 acres are proposed for treatment. Due to the minimal overlap, cumulative effects would be minimal.

In recent years, old growth habitats have been left unmanaged to maintain old growth characteristics. The absence of natural disturbances, such as large fires, occurring within the analysis area since 2000 has limited the type of habitat available for black-backed woodpeckers to general forest habitat. The action alternatives would remove old growth habitat, but KFP standards for old growth would be met and there are minimal, cumulative effects to this component of general forest habitat.

Normal road and trail maintenance activities have the potential to remove nesting and foraging trees if they are close to a trail or road and present a safety hazard. Similarly, firewood cutting would remove snags and would reduce nesting and foraging habitat availability along open roads. The decrease in habitat would be limited to areas within about 150 to 200 feet of open roads. This loss of snag habitat was accounted for in the analysis of available snag habitat.

Within the analysis area, continued development of private land is anticipated and, depending on the type of development, such as timber harvest, home construction or land clearing would reduce general forest habitat by varying levels. This loss of general forest habitat would have minimal effect on black-backed woodpecker populations. The existing situation on federal land provides adequate available habitat for black-backed woodpeckers based on the availability of potential territories that are of adequate size and available snag habitat of 71 and 90 percent in the Crazy and Silverfish PSUs, respectively, which are above the minimum needed of 40 percent. Proposed removal of vegetation associated with this project would result in a 6 percent reduction of general forest habitat and would not reduce areas of high quality habitat.

Similarly, other agency and public actions identified in Appendix E (description of ongoing and foreseeable actions) would have little to no effect on black-backed woodpeckers or their habitat as most activities would occur within general forest habitat. A 71 to 90 percent snag habitat level would be available following the past, present, and foreseeable actions. This snag habitat level would maintain minimum viable population levels of cavity nesting birds, including the black-backed woodpecker, and no adverse cumulative effects are expected.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8. In the proposed action, MMC did not propose to implement feasible measures to minimize effects on the black-backed woodpecker or all practicable measures to maintain and protect wildlife habitat. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would comply with 36 CFR 228.8. The agencies' alternatives would incorporate additional feasible and practicable measures to minimize adverse environmental impacts on wildlife habitat that benefit black-backed woodpecker, including minimizing the disturbance area in the agencies' mine alternatives and implementing a Vegetation Removal and Disposition Plan and Environmental Specifications in the agencies' transmission line alternatives.

National Forest Management Act/Kootenai Forest Plan

KFP - Forestwide Management Direction – KFP II-1 #6, #7, #8, #17, II-22 and 23

The KNF is directed to "identify, protect, and manage" habitat for sensitive species in order to assist in maintaining viable populations. The KFP contains the following goals and direction for sensitive species: "determine the status of sensitive species and provide for their environmental needs as necessary to prevent them from becoming threatened or endangered" (KFP Vol. 1, II-1 #6). All alternatives would meet this direction for the black-backed woodpecker.

b. #7 – *Maintain diverse age classes of vegetation for viable populations of all* existing native, vertebrate, wildlife species: The action alternatives would be consistent with KFP direction to maintain diverse age classes of vegetation for viable populations (KFP Vol. 1, II-1 #7).

#8 – *Manage for sufficient snags and snag replacement trees to maintain viable populations of snag-dependent species*: All action alternatives would be consistent with KFP direction for snags and down wood (see section 3.25.2.2, *Snags and Woody Debris*). In all combined mine-transmission line alternatives, a wide range of successional habitats, and associated amounts of down wood would be available.

22, 23 – Maintenance of viable populations of existing native and desirable nonnative vertebrate species, as monitored through indicator species, attained through the maintenance of a diversity of plant communities and habitats: See1.b. above for habitat diversity

Appendix 16 – Cavity Habitat (Snags and Down Wood): For cavity habitat, see #8 above.

Forest Service Sensitive Species Statement of Findings

The no action alternatives would not impact individual black-backed woodpeckers or their habitat within the analysis area, and would not contribute to a trend toward federal listing or cause a loss of viability to the population or species. ***All combined action alternatives may impact individual black-backed woodpeckers or their habitat, but will not likely contribute to a trend toward federal listing or cause a loss of viability to the population or species.*** This determination is based on: 1) no impact on high quality (post-fire) habitat would occur; 2) general forest habitat reduction would be 6 percent or less; 3) no black-backed woodpeckers have been observed in the Crazy or Silverfish PSU, despite several recent surveys; 4) individual nest trees or localized patches of insect infestation within the analysis area removed during project activities may disturb individuals or pairs.

3.25.4.4 Coeur D'Alene Salamander

3.25.4.4.1 Analysis Area and Methods

The analysis of potential impacts of the proposed project on individuals of the Coeur d'Alene salamander or their habitat is limited to where the Coeur d'Alene salamander could potentially occur, adjacent to Bear Creek Road (NFS road #278). Other areas of the analysis area do not provide suitable habitat for this species.

Coeur d'Alene salamander population ecology, biology, habitat description, and relationships identified by research are described in Cassirer *et al.* (1994), Maxell (2000), Maxell *et al*. (2003), and MNHP (2014a), which are incorporated by reference. Coeur d'Alene salamander occurrence data come from recent District wildlife observation records and KNF historical data (NRIS Wildlife), MNHP, and other agencies, such as FWP. The impacts analysis includes an evaluation of the benefits to the Coeur d'Alene salamander from mitigation measures proposed by the agencies such as implementation of a final Road Management Plan and a Vegetation Removal and Disposition Plan and adherence to INFS standards and guidelines and Montana water quality standards.

3.25.4.4.2 Affected Environment

The Coeur d'Alene salamander has been found below 5,000 feet in western Montana and is the only species of lungless salamander in the northern Rocky Mountain region (Cassirer *et al.* 1994). The salamander is associated with seepages, waterfalls, and small creeks near talus with fractured rock and with dense overstory canopies (Werner *et al.* 2004; MNHP 2014).

Johnson (1999) reports Coeur d'Alene salamander confirmed presence in four of the eight planning units on the KNF at 13 different sites. The salamander has been confirmed in two additional planning units since 1999 and the known sites total 36. The Coeur d'Alene salamander is lungless and respirates entirely through its skin. This necessitates moist conditions to prevent dessication and death. Known populations on the KNF are isolated by miles of dry, unsuitable habitat that cannot be crossed (Maxell 2000; Maxell *et al.* 2003).

Historical records show that Coeur d'Alene salamanders were observed prior to 1990 above and below the Bear Creek Road (NFS road #278) on the northwest side of Big Hoodoo Mountain. A single adult Coeur d'Alene salamander was recorded in 1989 adjacent to the Libby Creek Road (NFS road #231) about 1.5 miles northeast of MMC's proposed Little Cherry Creek Impoundment (Westech 2005a). No recent observations of the Coeur d'Alene salamander in the Crazy and Silverfish PSUs have been recorded (MNHP 2014). The site description for the Libby Creek record indicated it lacks the moist environment typical of Coeur d'Alene salamanders. The site could not be located during 2005 surveys (Westech 2005a). Where Coeur d'Alene salamanders were recorded adjacent the Bear Creek Road (NFS road #278), past timber harvest appears to have reduced canopy cover needed to ensure moist conditions (Westech 2005a).

3.25.4.4.3 Environmental Consequences

The transmission line alternatives, including construction of the Sedlak Park Substation and loop line, would not affect the Coeur d'Alene salamander due to the absence of nearby suitable habitat and are not included in the analysis.

Alternative 1 – No Mine

Alternative 1 would not disturb Coeur D'Alene salamanders or their habitat and would have no effect on this species.

Alternative 2 – MMC's Proposed Mine

According to Maxell (2000), the greatest threats to the Coeur d'Alene salamander are timber harvest, fire, road and trail development and maintenance, vehicle use on roads, and isolation of populations. About 10 miles of the Bear Creek Road (NFS road #278), from US 2 to the Bear Creek bridge, would be widened on its existing alignment and chip-sealed. The roadway width would be 20 to 29 feet wide and designed to handle speeds of 35 to 45 mph. The disturbed area, included ditches and cut-and-fill slopes, is expected to be up to 100 feet wide. Because the Bear Creek Road would be chip-sealed, use of mine or adit water and/or chemical stabilizers for dust suppression along the Bear Creek Road would be unlikely. Widening and improvement of the Bear Creek Road would affect 0.2 acres of wetlands along the road (see Table 184 in the *Wetlands and Other Waters of the U.S.* section) and may remove small areas of potential Coeur d'Alene salamander habitat. Some incidental mortality may occur due to forest clearing and increased traffic associated with Alternative 2. Although impacts on the Coeur d'Alene salamander are possible, they are not likely to occur because no Coeur d'Alene salamanders have been recently observed in the analysis area and because habitat in the analysis area does not appear to provide characteristics typically favored by this species, in particular adequate canopy cover to ensure moist conditions.

Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Impacts on the Coeur d'Alene salamander from Alternative 3 would be the same as Alternative 2, except that the likelihood of impacts would be less. The agencies' alternatives would include implementation of several measures that would further minimize adverse effects, if any, on the Coeur d'Alene salamander. MMC would implement a final Road Management Plan and a Vegetation Removal and Disposition Plan and comply with INFS standards and guidelines for any work in a RHCA along an access road.

Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Impacts on the Coeur d'Alene salamander from Alternative 4 would be the same as Alternative 3.

Cumulative Effects

Timber harvest has occurred in the analysis area since the 1950s and, up until the early 1990s, harvest occurred within riparian habitats resulting in alterations and reduction of riparian habitat. High levels of road construction to facilitate harvest occurred through the 1980s and resulted in sedimentation into streams. Detailed descriptions of previous vegetation and road management activities are found at the beginning of Chapter 3 and Appendix E lists all past actions considered in the cumulative effects analysis. Since the adoption of the KFP in 1986, application of KFP standards has resulted in the protection of riparian habitats, less road construction and road closures, and BMP work on existing roads to reduce sedimentation.

Alternative 1 would not have cumulative impacts on the Coeur d'Alene salamander. The likelihood of mine alternatives directly or indirectly affecting the Coeur d'Alene salamander is low. No other reasonably foreseeable actions would affect any known locations of Coeur d'Alene salamander. All mine alternatives would have no cumulative impacts on this species.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. All Mine Alternatives and Transmission Line Alternatives would comply with 36 CFR 228.8 with regard to effects to the Coeur d'Alene salamander.

National Forest Management Act/Kootenai Forest Plan

p. II-1 #6 – *Determine the status of sensitive species and provide for their environmental needs as necessary to prevent them from becoming threatened or endangered* and p. II-1 #7 – *Maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species:* Coeur d'Alene salamanders have not been documented in areas potentially affected by any of the mine or transmission line alternatives since 1990. The site above and below the Bear Creek Road (NFS road #278) where they were documented prior to 1990 does not appear to provide sufficient canopy cover or other conditions to ensure moist conditions required by Coeur d'Alene salamanders. The agencies' alternatives would include implementation of several measures that would further reduce any effects on the Coeur d'Alene salamander, specifically: 1) implementation of a final Road Management Plan and a Vegetation Removal and Disposition Plan, 2) the use of either a chemical stabilization, groundwater, or segregated mine or adit water with nitrate concentrations of 1 mg/L or less and with concentrations of all other parameters below the mine drainage ELG to control dust on mine access roads, and 3) as described in section 3.23, *Wetlands and Other Waters of the U.S.*, compliance with INFS standards and guidelines for any work in a RHCA along an access road.

KFP riparian standards and guidelines, KFP Vol. 1, II-28 thru 33, as amended by INFS: Compliance with INFS, including RHCA standards and guidelines, are discussed in detail in section 3.6, *Aquatic Life and Fisheries*.

Forest Service Sensitive Species Statement of Findings

The no action alternatives would not impact individual Coeur d'Alene salamanders or their habitat within the analysis area, and would not contribute to a trend toward federal listing or cause a loss of viability to the population or species. ***Although unlikely, Alternatives 2, 3, and 4 (action alternatives) may impact individual Coeur d'Alene salamanders or their habitat, and but would not likely contribute to a trend toward federal listing or cause a loss of viability to the population or species.*** This determination is based on: 1) Widening and improvement of the Bear Creek Road would affect 0.2 acres of wetlands along the road and may remove or degrade small areas of potential Coeur d'Alene salamander habitat, 2) Some incidental mortality could occur due to forest clearing and increased traffic associated with the mine alternatives, 3) No Coeur d'Alene salamanders have been observed in the analysis area since 1989, 4) Habitat in the analysis area does not appear to provide characteristics favored by this species, in particular moist conditions, and 5) the agencies' alternatives would include implementation of several measures that would further reduce the likelihood of any adverse effects on the Coeur d'Alene salamander, including implementation of a final Road Management Plan, a Vegetation Removal and Disposition Plan, and compliance with INFS standards and guidelines for any work in a RHCA along an access road.

State Requirements

Alternatives 3 and 4 would comply with the MMRA regarding disturbed lands being reclaimed to a post-mining land use with stability and utility comparable to that of the pre-mining landscape. Draft findings regarding compliance with MFSA requirements are discussed in the Summary, beginning on p. S-53.

3.25.4.5 Fisher

3.25.4.5.1 Regulatory Framework

In 2011, the USFWS determined that listing the fisher as threatened or endangered was not warranted at the time (USFWS 2011a). This finding was in response to a petition to list a distinct population segment of the fisher in its U.S. Northern Rocky Mountain range, including portions of Montana, Idaho, and Wyoming. The USFWS determined that fishers in the Northern Rocky Mountains met the definition of a distinct population segment because they are geographically separated from other fisher populations, and because the loss of this population would result in a significant gap in the range of the species and the loss of a unique genetic identity found nowhere else within the range of the species. Based on the existence of fisher throughout much of its historical range in Montana and Idaho, including "an increase in number and distribution since their perceived extirpation in the 1920s," and no indications that other natural or anthropogenic factors are likely to significantly threaten the existence of this distinct population segment of fisher, the USFWS concluded that the distinct population segment "is not now, or in the foreseeable future, threatened by other natural or anthropogenic factors affecting its continued existence, or that these factors act cumulatively with other potential threats, to the extent that listing under the Act [ESA] as an endangered or threatened species is warranted at this time" (USFWS 2011a).

3.25.4.5.2 Analysis Area and Methods

Fisher population ecology, biology, habitat description and relationships are described in Jones (1991), Powell (1993), Vinkey (2003), Lofroth *et al*. (2010), USFWS (2011a), and Raley *et al*. (2012). These provided guidance in evaluating potential habitat and effects to fisher, and are incorporated by reference. That information is incorporated by reference. Fisher occurrence data come from recent District wildlife observation records and KNF historical data (NRIS Wildlife) and other agencies, such as the FWP. Potential fisher habitat was recently modeled for Region One (USDA Forest Service 2012d, Ecosystems Research Group 2012) and includes old growth forest, as well as a diversity of forest successional stages and plant communities that provide seasonal fisher habitat and riparian areas that are important for travel, resting and denning. The modeling includes both National Forest System and private and State lands. Specific fisher habitat information is not available for private or state-owned lands in the analysis area, much of which has been logged in the past 20 to 30 years. Fisher habitat on private land was included in the Region One modeling.

The analysis area for the fisher is described in section 3.25.1, *Introduction.* The analysis area for determination of population trend and contribution toward population viability is the KNF.

The impacts analysis includes an evaluation of the benefits to fisher from mitigation measures proposed by the agencies such as implementation of a final Road Management Plan, a Vegetation Removal and Disposition Plan, and adherence to INFS standards and the agencies' Environmental Specifications (Appendix D) or MMC's Environmental Specifications (MMI 2005b).

3.25.4.5.3 Affected Environment

In the western United States, fishers prefer late-successional forests (mature or old growth forests), and low elevation, moist riparian corridors for resting, denning, and travel (Heinemeyer and Jones 1994). The fisher feeds on a variety of prey, from small to medium-sized mammals, birds, and carrion (Powell and Zelinski 1994). Fishers use an assortment of habitats for feeding, although they avoid non-forested areas (Jones and Garton 1994, and Roy 1991). Complex forest structure such as large snags, large down wood material, and high canopy cover are important components of fisher habitat.

In the western United States, fisher populations are limited to certain mountain ranges in the Pacific Northwest and Rocky Mountains. Fisher distribution in United States Northern Rocky Mountains is thought to be similar to the presumed historical range (USFWS 2011a). These isolated populations may be acutely susceptible to local extinction (Heinemeyer and Jones 1994). Fishers once occurred in the Cabinet Mountains, but were eliminated locally by overtrapping and habitat alteration (Ruggiero *et al.* 1994; Vinkey *et al.* 2006). Between 1989 and 1991, 110 fishers from the Midwest were released in the Cabinet Mountains as part of a state translocation program. Vinkey (2003) studied the distribution of fishers in the Cabinet Mountains using winter snow tracking, track plates, and live-trapping surveys conducted from 2001 to 2003. All verified records of fishers from this study were from the west Cabinet Mountains. Vinkey (2003) concluded that the introduction of fishers to the Cabinet Mountains has established a small population, but that the long-term viability of this population is uncertain. Similarly, surveys for fishers in the Northern Rockies since 2004 has only detected fishers at 222 out of 4,813 snares deployed in eight years (Schwartz *et al*. 2006, USDA Forest Service 2012d). The KNF provides suitable fisher habitat, but both current and historical information suggests that fisher have never been abundant in the Cabinet Mountains (Heinz 1996; Vinkey 2003). The current population of fishers in the Cabinet Mountains is unknown. Fishers are generally more common where human density is low and human disturbance is reduced (Ruggiero *et al.* 1994).

Johnson (1999) reported fisher presence was confirmed in five of the eight planning units on the KNF. Fisher observation and monitoring data indicates that suitable habitat is present within the analysis area, especially along forested streams. There have been no recent (since 2000) sightings of fishers within the analysis area, but historical observations have been recorded within the Crazy and Silverfish PSUs. A fisher den was found in 1989 near Horse Mountain (Roy 1991). Fishers are known to be present within the Libby Creek drainage, and are possibly present within the Poorman Creek, Ramsey Creek, and West Fisher Creek drainages (Westech 2005a).

Ruediger (1994) reported the KNF as a primary habitat area for fisher. More recently, fisher habitat was modeled for Region One and is found within the analysis area (USDA Forest Service 2012d). Forestwide, fisher habitat is abundant at 703,423 acres and exceeds the upper range of historic variation of 671,150 acres (Ecosystems Research Group 2012). Although fisher are found within landscapes that have high levels of contiguous cover and mid to late seral conditions, their home ranges include a diversity of forest successional stages and plant communities (Lofroth *et al*. 2010, Raley *et al*. 2012). Some studies have shown positive association with young successional stages such as pole-sapling and young forest (*e.g.*, Jones 1991), possibly because of prey resources associated with these environments. In particular, Jones (1991) observed fisher shifting their use of habitat seasonally, with mature and old-growth forests being used in the summer and young forest cover types used more in the winter. Riparian areas are important habitat for travel, resting, and denning. Based on habitat modeling, 19,178 acres of potential yearlong fisher habitat occur in the Crazy PSU and 13,262 acres in the Silverfish PSU, including state and private lands. The Crazy PSU is within the Kootenai planning unit, and the Silverfish PSU is within the Fisher planning unit. Following the identification process outlined in Ruediger (1994), these planning units are designated as secondary fisher conservation areas (Johnson 2004b). The Crazy and Silverfish PSUs are considered high-quality fisher habitat areas (Ibid.).

Old growth habitat on private and State land in the analysis area consists mostly of cottonwood/ spruce riparian habitat. The majority of the private and State lands in the analysis area has high road densities and has been logged in the past 20 to 30 years (Figure 85), resulting in fragmented forest habitat. Based on recent modeling, potential fisher habitat on private and State lands is limited and of marginal quality (USDA Forest Service 2012d).

FWP currently manages the species as a furbearer with a limited harvest of 7 animals in 2014.

3.25.4.5.4 Environmental Consequences

Alternative 1 – No Mine

Alternative 1 would not disturb the fisher or its habitat and would have no effect on this species (Table 219). Over time, with continued fire suppression and lack of active forest management, indirect effects of this alternative would include a continued trend toward later successional habitats, which would favor fisher habitat. Large-scale fires could potentially occur in the analysis area. Over the next five decades, Ecosystems Research Group (2012) reported that the driving force behind habitat change on the KNF is due to natural disturbance processes, especially wildfire. Similarly, the USFWS 2011a listing decision notes that fisher populations have increased in numbers and distribution despite the effects of anthropogenic activities.

Alternative 2 – MMC's Proposed Mine

No impacts on fisher would occur as a result of Alternative 2 in the Silverfish PSU. Alternative 2 would reduce the amount of yearlong fisher habitat in the Crazy PSU by 746 acres, or 4 percent of the habitat available. Winter fisher habitat would be reduced by 1,798 acres or about 12 percent of the winter habitat available (Table 219). Most of the habitat impacts to both yearlong and winter habitat would be in the Little Cherry Creek Tailings Impoundment Site.

Table 219. Available Fisher Habitat and Potential Effects in the Analysis Area by Mine Alternative.

Measurement Criteria	[1] No Mine/Existing Conditions	[2] MMC's Proposed Mine	[3] Agency Mitigated Poorman Impoundment	[4] Agency Mitigated Little Cherry Creek Impoundment
Crazy PSU				
Yearlong Habitat (acres)	19,178	18,432 (746/3.9)	18,690 (488/2.5)	18,644 (534/2.8)
Winter Habitat (acres)	14,722	12,924 (1,798/12.2)	13,686 (1,036/7.0)	13,369 (1,353/9.2)
Silverfish PSU				
Yearlong Habitat (acres)	13,262	13,262 (0/0)	13,262 (0/0)	13,262 (0/0)
Winter Habitat (acres)	12,964	12,964 (0/0)	12,964 (0/0)	12,964 (0/0)

Number in parentheses is the reduction in habitat acres/percent in habitat area compared to existing conditions.
Source: GIS analysis by ERO Resources Corp. using KNF data.

The risk of fisher mortality would increase as a result of increased traffic and increased winter access to fisher habitat from Alternative 2. Alternative 2 would include snowplowing Bear Creek Road (NFS road #278) and Libby Creek Road (NFS road #231) during the evaluation program, and while the Bear Creek Road is reconstructed, allowing trappers easy winter access to old growth and riparian areas providing good fisher habitat. Trapping has a negligible impact on fisher populations in the KNF. The annual quota for fisher across FWP Region 1 is just two animals, mostly from the Flathead and Whitefish areas.

Annual traffic would be about three times existing levels throughout the life of the mine (Table 172). The increase in traffic in Alternative 2 would substantially increase the risk of increased fisher mortality. MMC would provide transportation to employees using buses, vans, and pickup trucks thereby limiting the use of personal vehicles. MMC would limit concentrate haulage to daylight hours during the day shift (0800 to 1630), which would minimize vehicular-fisher collisions during the early morning, evening and night time-periods. MMC would report road-killed animals to the FWP as soon as road-killed animals were observed. The FWP would either remove road-killed animals or direct MMC how to dispose of them. Increased traffic noise may also displace fishers from suitable habitat. When the mill ceased operations in the Closure Phase, mine traffic volume would be substantially less than shown in Table 171. Future traffic volume when all activities at the mine are completed in the Post-Closure Phase would be higher than in Alternative 1 because of reconstruction of Bear Creek Road and loss of the Little Cherry Loop Road beneath the impoundment. Mortality risk to fisher would decrease on the Bear Creek Road compared to operations, but the permanently improved road conditions (increased road width, improved sight distance, paving) and higher traffic speeds that would continue Post-Closure would result in a permanently higher fisher mortality risk compared to pre-mine conditions. All action alternatives would include snowplowing the Libby Creek Road (NFS road #231) during the Evaluation Phase and while the Bear Creek Road was reconstructed, providing trappers easier winter access to fisher habitat in old growth and riparian areas. A gate would limit motorized access to snowplowed areas.

While not highly sensitive to human activity, the fisher is a species that generally avoids humans (Powell 1993). Disturbance effects may occur due to the presence of people and machines during construction and operations, potentially displacing fishers from nearby suitable habitat. Displacement effects would probably be the greatest during the Construction Phase, but would continue at lower levels during operations. According to Heinemeyer and Jones (1994), the most sensitive time for fishers is the breeding, denning, and rearing period (February 15 to June 30).

Impacts within 200 meters of perennial streams are especially important to avoid (Ibid.). Impacts of Alternative 2 on riparian fisher habitat may be reduced through implementation of MMC's proposed Wetland Mitigation Plan. The feasibility of MMC's proposed Wetland Mitigation Plan to replace the lost functions of all potentially affected wetlands is uncertain. MMC's plan is conceptual and would be refined during the 404 permitting process. MMC did not update its mitigation plan for Alternative 2 to reflect new wetland and stream mitigation regulations and procedures. Section 3.23, *Wetlands and Other Waters of the U.S.*, discusses proposed wetland mitigation in more detail. MMC would store mine, adit, or tailings water at the Ramsey Plant Site, a surge pond at the LAD Areas, and the tailings impoundment. The metals in the tailings water would be similar to what is found at the Troy Mine decant ponds (see Table 120 in the *Water Quality* section), where adverse effects on wildlife have not been observed (USDA Forest Service and DEQ 2012). Concentrations of metals in mine and adit water, which would be stored in mine/yard pond at the Ramsey Plant Site and in a surge pond at the LAD Areas, would be lower than tailings water (see Table 120 in the *Water Quality* section). The Ramsey Plant Site would be fenced, restricting deer access.

Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

The types of impacts on fisher from Alternative 3 would be the same as Alternative 2, except that less yearlong and winter fisher habitat would be affected (488 and 1,036 acres, respectively) (Table 219). Yearlong habitat would be reduced 2.5 percent and winter habitat reduced 7.0 percent from existing conditions. The agencies' mine alternatives would have fewer disturbances in RHCAs and other riparian areas, minimizing effect on the fisher. The effect of increased traffic on the Bear Creek Road would be the same as Alternative 2. MMC would remove big game animals killed by any vehicles daily from road rights-of-way within the permit area and along roadways used for access or hauling ore (NFS roads #231, #278, #4781, and #2316 and new roads built for the project) for life of mine. MMC also monitor the number of big game animals killed by vehicle collisions on these roads and report findings annually. These measures would minimize fisher mortality along the access road.

Impacts of Alternative 3 on riparian fisher habitat would be minimized through implementation of the agencies' proposed Wetland Mitigation Plan, which would have a greater likelihood of replacing lost functions than the Alternative 2 Wetland Mitigation Plan. The agencies' alternatives would include implementation of several measures that would further minimize adverse effects, if any, on the fisher. MMC would implement a final Road Management Plan and a Vegetation Removal and Disposition Plan and comply with INFS standards and guidelines for any work in a RHCA along an access road. Habitat acquisitions and road closures associated with grizzly bear mitigation would also benefit fisher. Road closures would reduce trappers' winter access to fisher habitat in old growth and riparian areas.

Water management in Alternatives 3 and 4 would reduce the risk to wildlife from contaminant uptake from storage of mine, adit, and tailings water. All mine and adit water would be treated and discharged at the Libby Adit Water Treatment Plant and not stored in ponds. The LAD Areas would not be used and the surge ponds would not pose a risk to the fisher. Tailings water quality would have lower metal concentrations than in Alternative 2; the factors leading to lower metal concentrations in tailings water quality in Alternatives 3 and 4 are discussed in the *Water Quality* section, p.674.

Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

Impacts on fisher from Alternative 4 would be about the same as Alternative 3, except that slightly more yearlong and winter fisher habitat would be affected (534 and 1,353 acres, respectively) (Table 219). Yearlong habitat would be reduced 2.8 percent and winter habitat reduced 9.2 percent from existing conditions. The effect of mitigation on the fisher would be the same as Alternative 3.

Alternative A – No Transmission Line

Table 220 summarizes the changes in yearlong and winter habitat due to each alternative. Alternative A would not disturb the fisher or its habitat and would have no effect on this species.

Alternative B – MMC’s Proposed Transmission Line (North Miller Creek Alternative)

Alternative B would reduce the amount of yearlong and winter fisher habitat by less than 1 percent in both the Crazy PSU and Silverfish PSUs. Yearlong and winter fisher habitat would be reduced by 42 and 39 acres, respectively in the Crazy PSU; and 6 and 39 acres in the Silverfish PSU, respectively (Table 220). The risk of fisher mortality may increase as a result of increased construction traffic from any of the action alternatives, including Alternative B. Traffic increases are anticipated to be minimal during the 2-year transmission line construction and 1-year decommissioning periods. While not highly sensitive to human activity, the fisher is a species that generally avoids humans (Powell 1993). Disturbance effects could occur due to the presence of people and machines during transmission line construction, potentially displacing fishers from nearby suitable habitat. According to Heinemeyer and Jones (1994), the most sensitive time for fishers is the breeding, denning, and rearing period (February 15 to June 30). Displacement effects would be negligible during operations because activities would be limited to line maintenance. Alternative B would affect about 1 acre of coniferous forest and 4 acres of old growth providing fisher habitat on private land. Because fisher habitat on private land, including in the Sedlak Park Substation and loop line footprint, is of marginal quality, impacts on fisher would be minimal. MMC’s Environmental Specifications (MMI 2005b) included limited measures that would protect riparian habitat.

Table 220. Available Fisher Habitat and Potential Effects in the Analysis Area by Transmission Line Alternative.

Measurement Criteria	[A] No Transmission Line	[B] North Miller Creek	[C-R] Modified North Miller Creek	[D-R] Miller Creek	[E-R] West Fisher Creek
Crazy PSU					
Yearlong Habitat (acres)	19,178	19,136 (42/0.2)	19,149 (29/0.2)	19,142 (36/0.2)	19,142 (36/0.2)
Winter Habitat (acres)	14,722	14,682 (39/0.3)	14,706 (16/0.1)	14,699 (23/0.2)	14,699 (23/0.2)
Silverfish PSU					
Yearlong Habitat (acres)	13,262	13,256 (6/<0.1)	13,254 (8/<0.1)	13,220 (42/0.3)	13,200 (62/0.5)
Winter Habitat (acres)	12,964	12,925 (39/0.3)	12,929 (35/0.3)	12,904 (60/0.5)	12,922 (42/0.3)

Number in parentheses is the reduction in habitat acres/percent in habitat area compared to existing conditions.
Source: GIS analysis by ERO Resources Corp. using KNF data.

Alternative C-R – Modified North Miller Creek Transmission Line Alternative

Impacts on fisher from Alternative C-R on National Forest System land would be similar to Alternative B, except that slightly less yearlong and winter fisher habitat would be impacted. Yearlong and winter fisher habitat would be reduced by 29 and 16 acres, respectively in the Crazy PSU; and 8 and 35 acres in the Silverfish PSU, respectively (Table 220). Due to lack of suitable habitat, construction of the Sedlak Park Substation and loop line would not affect fishers.

Impacts of Alternative C-R on riparian fisher habitat would be minimized through implementation of the agencies' Vegetation Removal and Disposition Plan, and the agencies' Environmental Specifications (Appendix D). The agencies' Environmental Specifications describe mitigation activities that would benefit fisher, including locating structures outside of riparian forest, minimizing clearing of riparian forests and the use of heavy equipment in these areas, restoring degraded riparian habitats and improving passage for terrestrial wildlife along riparian corridors. One of the goals of the Vegetation Removal and Disposition Plan would be to minimize vegetation clearing. The plan would identify areas where clearing would be avoided, such as deep valleys with high line clearance, and measures that would be implemented to minimize clearing. It would evaluate the use of monopoles to reduce clearing in select areas, such as old growth. For example, the growth factor used to assess which trees would require clearing could be reduced in sensitive areas, such as RHCAs, from 15 years to 5 to 8 years. Reducing the growth factor could reduce clearing width, but increase maintenance costs. Heavy equipment use in RHCAs would be minimized. Shrubs in RHCAs and in the line of sight between the line and private land would be left in place unless they had to be removed for safety reasons.

Alternative D-R – Miller Creek Transmission Line Alternative

Impacts on fisher from Alternative D-R on National Forest System land would be similar to Alternative B. Alternative D-R would reduce the amount of yearlong and winter fisher habitat by less than 1 percent in both the Crazy PSU and Silverfish PSUs. Yearlong and winter fisher habitat would be reduced by 36 and 23 acres, respectively in the Crazy PSU; and 42 and 60 acres, respectively in the Silverfish PSU (Table 220). The acres impacted by Alternative D-R in the

Silverfish PSU would be slightly greater than Alternative B, but still less than 1 percent of the habitat available. Due to lack of suitable habitat, construction of the Sedlak Park Substation and loop line would not affect fishers. The mitigation measures described for Alternative C-R would be implemented in Alternative D-R.

Alternative E-R – West Fisher Creek Transmission Line Alternative

Impacts on fisher from Alternative E-R on National Forest System land would be similar to Alternative D-R except that the relative effects to yearlong and winter fisher habitat vary slightly in the Silverfish PSU. Alternative E-R would reduce the amount of yearlong and winter fisher habitat by less than 1 percent in both the Crazy PSU and Silverfish PSUs. Yearlong and winter fisher habitat would be reduced by 36 and 23 acres, respectively in the Crazy PSU; and 60 and 42 acres, respectively in the Silverfish PSU (Table 220). Due to lack of suitable habitat, construction of the Sedlak Park Substation and loop line would not affect fishers. The mitigation measures described for Alternative C-R would be implemented in Alternative E-R.

Combined Mine-Transmission Line Effects

Alternative 2B would have the greatest impacts on fisher habitat in the Crazy PSU, impacting 783 acres (4.1 percent) of yearlong habitat and 1,826 acres (12.4 percent) of winter habitat. Alternatives 3C-R, 3D-R, and 3E-R would impact between 517 and 524 acres (2.7 percent of habitat available), and Alternatives 4C-R, 4D-R, and 4E-R would affect 563 and 571 acres (2.9 to 3.0 percent of habitat available) of yearlong fisher habitat in the Crazy PSU (**Error! Reference source not found.**). Impacts on both yearlong and winter fisher habitat in the Silverfish PSU for the other combined mine transmission line alternatives would all be less than 1 percent of the habitat available, range from 8 to 62 acres or yearlong habitat and 35 to 60 acres of winter habitat. Due to lack of suitable habitat, construction of the Sedlak Park Substation and loop line would not affect fishers. All combined action alternatives would fragment fisher habitat through the reduction of habitat and placement of human structure on the landscape. Although habitat fragmentation would increase, sufficient habitat would remain to provide connectivity to the species.

In all combined action alternatives, the risk of fisher mortality would increase as a result of increased traffic and increased access to fisher habitat. Annual traffic on the mine access road (Bear Creek Road) would be about three times existing levels throughout the life of the mine (Table 171 in the *Transportation* section), increasing the mortality risk. Increased traffic noise may also displace fishers from suitable habitat. All combined action alternatives would include snowplowing the Libby Creek Road (NFS road #231) during the Evaluation Phase and while the Bear Creek Road was reconstructed, providing trappers easier winter access to fisher habitat in old growth and riparian areas. Gates would limit motorized access. While research does not show fishers to be highly sensitive to human activity, disturbance effects could occur due to the presence of people and machines during transmission line construction, potentially displacing fishers from nearby suitable habitat. According to Heinemeyer and Jones (1994), the most sensitive time for fisher is the breeding, denning, and rearing period (February 15 to June 30). In Alternative 2B, impacts on riparian fisher habitat would be reduced through implementation of MMC's proposed wetland mitigation and Environmental Specifications (MMI 2005b). Impacts of the agencies' combined alternatives would be more effectively minimized through the agencies' Wetland Mitigation Plan and Vegetation Removal and Disposition Plan, and the Environmental Specifications (Appendix D), as described above. Impacts on fisher habitat would be somewhat reduced through MMC's and the agencies' proposed land acquisition associated with grizzly bear mitigation. Acquired parcels would be managed for grizzly bear use in perpetuity and may improve or contribute suitable fisher habitat if the acquired parcels provided appropriate habitat characteristics. Road closures would reduce trappers' winter access to fisher habitat in old growth and riparian areas.

Cumulative Effects

Past actions, including detailed descriptions of previous vegetation and road management activities, are described in section 3.2, *Past and Current Actions*, shown on Figure 50, and listed in Appendix E. Past actions, such as timber harvest, road construction, and fire-suppression activities, have altered the old growth ecosystems in the analysis area, resulting in a reduction in early and late succession habitats; conditions favoring shade-tolerant, fire-intolerant species; loss of large snags and down wood; increases in tree density, and a shift to a largely mid-seral structural stage (USDA Forest Service 2003b). Continuing development of private lands, including timber harvest, home construction, and land clearing would contribute to losses of fisher habitat in the analysis area. Impacts on fisher on private and State lands would probably be minimal because it is likely that fisher habitat in these areas is of marginal quality.

Future actions that may further reduce fisher habitat in the analysis area include the Miller-West Fisher Vegetation Management Project, the Coyote Improvement Vegetation Management Project and the Silverbutte Bugs timber sale. Forest treatments proposed for these vegetation management projects, could contribute to cumulative losses and fragmentation of fisher habitat. The projects will not directly impact old growth that could provide potential fisher habitat. Surface impacts from other reasonably foreseeable actions in the analysis area would be minimal.

Other cumulative effects include existing road and associated traffic volume, primarily on US 2, and existing roads and human disturbance in the analysis area. If timber harvest activities occurred concurrently with mine or transmission line construction and operations, higher traffic volume and associated increased fisher mortality risk may occur. No other past, current, or reasonably foreseeable actions are anticipated to contribute to cumulative impacts on fishers.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. Mine Alternative 2 and Transmission Line Alternative B would not fully comply with 36 CFR 228.8. In the proposed action, MMC did not propose to implement feasible measures to minimize effects on the fisher or all practicable measures to maintain and protect wildlife habitat. The agencies' alternatives (Mine Alternatives 3 and 4 and Transmission Line Alternatives C-R, D-R, and E-R) would comply with 36 CFR 228.8. These alternatives would incorporate additional feasible and practicable measures to minimize adverse environmental impacts on wildlife habitat that benefit fisher. These measures would include substantially reducing disturbance in yearlong and winter habitat in the mine area, reducing effects on old growth, locating structures outside of riparian forest, minimizing clearing of riparian forests and the use of heavy equipment in these areas, restoring degraded riparian habitats and improving passage for terrestrial wildlife along riparian corridors.

Table 221. Available Fisher Habitat and Potential Effects in the Analysis Area by Combined Mine-Transmission Line Alternative.

Measurement Criteria	[1] No Mine Existing Condition	[2] MMC's Proposed Mine	[3] Agency Mitigated Poorman Impoundment Alternative			[4] Agency Mitigated Little Cherry Creek Impoundment Alternative

Yearlong Habitat (acres)	19,178	18,395 (783/4.1)	18,661 (517/2.7)	18,654 (524/2.7)	18,654 (524/2.7)	18,615 (563/2.9)	18,607 (571/3.0)	18,607 (571/3.0)
Winter Habitat (acres)	14,722	12,896 (1,826/12.4)	13,674 (1,048/7.1)	13,666 (1,056/7.2)	13,666 (1,056/7.2)	13,357 (1,365/9.3)	13,350 (1,372/9.3)	13,350 (1,372/9.3)
Silverfish PSU								
Yearlong Habitat (acres)	13,262	13,256 (6/<0.1)	13,254 (8/0.1)	13,220 (42/0.3)	13,200 (62/0.5)	13,254 (8/0.1)	13,220 (42/0.3)	13,200 (62/0.5)
Winter habitat (acres)	12,964	12,925 (39/0.3)	12,929 (35/0.3)	12,904 (60/0.5)	12,922 (42/0.3)	12,929 (35/0.3)	12,904 (60/0.5)	12,922 (42/0.3)

Number in parentheses is the reduction in habitat acres/percentage compared to existing conditions.

Source: GIS analysis by ERO Resources Corp. using KNF data.

National Forest Management Act/Kootenai Forest Plan

p.II-1 #6 – *Determine the status of sensitive species and provide for their environmental needs as necessary to prevent them from becoming threatened or endangered*: Fisher habitat occurs within the analysis area. In Mine Alternative 2 and Transmission Line Alternative B, MMC did not propose to implement practicable measures to minimize effects on the fisher. The agencies' alternatives would include measures to minimize effect on the riparian and old growth forest that provide habitat for fisher. ***All alternatives may impact individual fishers or their habitat within the analysis area, but would not contribute to a trend toward federal listing or cause a loss of viability to the population or species.***

p.II-1 #7 – *Maintain diverse age classes of vegetation for viable populations of all existing native, vertebrate, wildlife species:* All action alternatives would maintain diverse age classes for viable populations of the fisher.

p. II-22 – *Maintenance of 10 percent of the KNF land base below 5,500 feet in old-growth condition that is representative of the major forest types, spread evenly through most major drainages, and providing for old-growth dependent wildlife species:* Transmission Line Alternatives C-R and D-R would avoid old growth habitat on private land. All action alternatives would require a project-specific amendment to allow harvest within designated old growth stands (MA 13). The project-specific amendment would change the current MA 13 (Old Growth) allocation of all harvested stands to either MA 23 (Electric Transmission Corridor) or MA 31 (Mineral Development). The action alternatives would result in between 16.8 and 16.9 percent designated old growth below 5,500 feet elevation in the Crazy PSU, and 13.6 percent designated old growth below 5,500 feet elevation in the Silverfish PSU. All action alternatives would be consistent with KFP direction to maintain a minimum of 10 percent old growth below 5,500 feet in elevation in each third order drainage or compartment, or a combination of compartments.

p.II-22, 23 – *Maintenance of viable populations of existing native and desirable non-native vertebrate species, as monitored through indicator species, attained through the maintenance of a diversity of plant communities and habitats:* See #7. above for habitat diversity.

Compliance with the INFS and RHCA standards and guidelines is discussed in section 3.6, *Aquatic Life and Fisheries*.

Forest Service Sensitive Species Statement of Findings

The no action alternatives would not impact individual fisher or their habitat within the analysis area, and would not contribute to a trend toward federal listing or cause a loss of viability to the population or species. ***All combined action alternatives may impact individual fishers or their habitat, but will not likely contribute to a trend toward federal listing or cause a loss of viability to the population or species for fishers.*** This determination is based on: 1) the mine alternatives would have no impact on fishers in the Silverfish PSU; 2) all combined action alternatives would result in the direct loss of fisher habitat, but these impacts represent less than 1 percent of potential fisher habitat; 3) all action alternatives could result in an increase in the risk of fisher mortality due to increased traffic and winter access to fisher habitat; 4) all action alternatives would result in increased habitat fragmentation and disruption of movement in riparian corridors, and potential displacement from suitable habitat due to human disturbance; and 5) all combined mine-transmission line alternatives would be consistent with KFP direction to maintain a minimum of 10 percent old growth (fisher habitat) below 5,500 feet in elevation. While some individuals could be affected, impacts would not be severe enough to limit fisher viability on the KNF. Given the availability of habitat, these impacts would not affect fisher populations in either the Crazy or Silverfish PSU.

State Requirements

Alternatives 3 and 4 would comply with the MMRA regarding disturbed lands being reclaimed to a post-mining land use with stability and utility comparable to that of the pre-mining landscape. Draft findings regarding compliance with MFSA requirements are discussed in the Summary, beginning on p. S-53. Trapping is managed by FWP. Proposed actions would not prevent the state from continuing to manage this species as a harvestable population.

3.25.4.6 Flammulated Owl

Flammulated owls are cavity-dependent owls that inhabit mostly mature to old ponderosa pine and ponderosa pine/Douglas-fir stands with low to medium stem densities. They are migratory and are found on the KNF from May to mid-October. These small owls are strongly dependent on large-diameter trees (generally 18 inches DBH or more), especially for nesting habitat, and prefer open stands with understory grass species for hunting moths and other insects. Pockets of dense understory conifer thickets are important for roosting, thermal and escape cover. Detailed flammulated owl population ecology, biology, habitat description and relationships identified by research are summarized in Hayward and Verner (1994). More recent research on nesting, food habits, home range and territories, and habitat quality conducted in Colorado, Idaho, and Montana is discussed in Linkhart (2001), Linkhart and Reynolds (1997), Linkhart *et al.* (1998), Groves *et al.* (1997), Powers *et al.* (1996), Wright (1996) and Wright *et al.* (1997). These provided guidance in evaluating potential habitat and potential effects to flammulated owls, and are incorporated by reference. In general, flammulated owls typically favor dry, relatively open forest at low to moderate elevation, generally dominated by ponderosa pine and Douglas-fir. They are obligate cavity nesters, generally using holes excavated by pileated woodpeckers or common flickers. Territory size during the nesting season averages about 40 acres (Hayward and Verner 1994). They feed primarily on moths and, in some areas, grasshoppers and cricket). They are neotropical migrants, breeding in North America as far north as southern British Columbia, Canada and at least as far south as Mexico and winter as far south as Guatemala (Hayward and Verner 1994).

3.25.4.6.1 Analysis Area and Methods

Flammulated owl occurrence data come from recent District wildlife observation records and KNF historical data (NRIS Wildlife). Potential flammulated owl habitat was mapped using TSMRS/FACTS vegetation data and photo-interpreted timber strata on private lands. Dry habitat types containing mature stands of ponderosa pine and/or Douglas-fir with relatively open canopies were identified.

The amount of habitat available in PSUs where activities are proposed was mapped and evaluated for potential effects to habitat due to facility siting, clearing associated with transmission line siting and installation and activities associated with road construction and widening. Effects of the alternatives were evaluated based on changes in habitat and potential disturbance during the breeding season.

The analysis area for project impacts and cumulative effects to individuals and their habitat consists of the Crazy, Silverfish, McElk, and Riverview PSUs. The analysis area includes private and State lands crossed by the various transmission line alternatives. The analysis area includes the PSUs impacted by proposed activities. While the bulk of activities occur within the Crazy and Silverfish PSUs, there are also project activities within McElk, Riverview, Treasure, and Rock PSUs. The analysis area boundary for direct effects is the proposed activity areas, as activities and alteration of the habitat would affect suitability for different species. The acres directly impacted by activities are put into the context of the PSU scale to provide a consistently sized analysis unit and better gauge the relative impacts of the activities. The boundaries for indirect and cumulative effects are the planning subunits that contain the analysis area as alteration of habitat could affect the availability and use of habitats. Analysis at the PSU scale allows the effects of the proposed activities to be put into context and their relative impacts gauged. The impacts to the Rock PSU are limited to a less than 1 acre of patch of steep, rocky ground, the impacts are nearly undetectable at the PSU scale, and therefore this PSU is not carried forward in detailed analysis.

3.25.4.6.2 Affected Environment

The KNF provides about 40,000 acres of potential flammulated owl habitat (Ecosystem Research Group 2012) and potential flammulated owl habitat occurs across all eight planning units (Johnson 1999). Field surveys have confirmed flammulated owl presence in five of eight planning units (Johnson 1999). The owl population size on the KNF is unknown (Ibid.). Flammulated owl surveys using taped owl calls to draw a response from nesting birds have been conducted intermittently within the Crazy and Silverfish PSUs over the last decade. The probability of detecting a male Flammulated Owl varies considerably depending on the nesting phase: from 100 percent detection probability during pair bonding and incubation, to 80 – 35 percent detection probability during brooding, to less than 15 percent detection probability during the post-fledgling period (Barnes and Belthoff 2008). Weather may also influence the timing of the breeding season (Fylling *et al.* According to District flammulated owl observation and monitoring data, the species has been observed on numerous occasions in the past 13 years in the North Fork Miller Creek and the Miller Creek drainages. No observations of flammulated owls have been recorded within the Crazy PSU. No flammulated owls were found during surveys conducted in 2005 (Westech 2005a) in the Crazy and Silverfish PSUs. As part of the Northern Region Landbird Monitoring program, forest-wide flammulated owl surveys were conducted in 2005 (Cilimburg 2006) and 2007 (Smucker and Cilimburg 2008) on the KNF. These surveys included the Teeters Peak area (NFS road #231) and Miller Creek (NFS roads #4725 and #4724,) with the species being detected along the North and South Fork Miller Creek roads (#4725 and #4724).

Mapped habitat from the KNF TSMRS/FACTS and timber strata/habitat type data indicate about 265 acres of potential flammulated owl habitat occur in the Crazy PSU, 581 acres in the Silverfish PSU, 2,490 acres in the Riverview PSU, 70 acres in the Treasure PSU and 3,368 acres in the McElk PSU. Of the 6,774 acres in the affected PSUs, 2,478 acres of potential habitat occur on National Forest System lands. Recent habitat analysis of forest-wide habitat (Ecosystem Research Group 2012) predicts an increase in actual and potential flammulated owl habitat over the next 5 decades.

The majority of the private lands in the analysis area has high road densities and the lands have been logged in the past 20 to 30 years, resulting in loss of snags and fragmented forest habitat. Coniferous forest on private lands is primarily dominated by dry ponderosa pine/Douglas-fir communities.

3.25.4.6.3 Environmental Consequences

Impacts on flammulated owls from mine and transmission line alternatives are shown in Table 222, and are described in the following subsections. Impacts from the mine alternatives would not affect flammulated owl habitat in any of the potentially affected PSUs.

Alternative 1 – No Mine

Impacts on potential flammulated owl habitat caused by the mine alternatives would not directly affect flammulated owl habitat. Alternative 1 would not impact flammulated owls or their habitat.

Alternative 2 – MMC's Proposed Mine

There is no identified flammulated owl habitat associated with any facilities (adit, tailings impoundment, or associated roads) proposed in Alternative 2. Alternative 2 would not directly affect flammulated owl habitat.

Alternative 2 would include tree clearing within disturbance boundaries. There is no identified potential flammulated owl habitat within the footprint of facilities including the adit or tailings impoundments. There would be no direct effects to the species due to clearing at these sites. Noise and other human-caused disturbances, such as blasting, construction of the plant and adit sites, road construction and use, and plant and adit operations could result in disturbance to nearby habitat, at least temporarily. Ambient illumination may disrupt orientation in nocturnal animals and competitive and predator-prey interactions (Longcore and Rich 2004). Lighting from permanent facilities could disrupt normal nocturnal activities of any nearby flammulated owls. One block of potential habitat is 0.25 mile north of the Little Cherry Creek Tailings Impoundment Site. Flammulated owls appear to be relatively tolerant of disturbance during the nesting season (Linkhart *et al.* 1998), and it is likely that low intensity activities of tailings-related operations would not unduly affect suitability of that habitat block. Disturbance impacts would likely be greatest during the Construction Phase, but could persist at lower intensities through mine operations.

Table 222. Effects on Flammulated Owl Habitat in the Analysis Area by Transmission Line Alternative.

Measurement Criteria	[A] No Transmission Line	[B] North Miller Creek	[C-R] Modified North Miller Creek	[D-R] Miller Creek	[E-R] West Fisher Creek
Crazy PSU					
Flammulated Owl Habitat (acres/%)	265	265	265	265	265
McElk PSU					
Flammulated Owl Habitat (acres/%)	3,368	3,360 (8/<1%)	3,360 (8/<1%)	3,360 (8/<1%)	3,360 (8/<1%)
Riverview PSU					
Flammulated Owl Habitat (acres/%)	2,490	2,485 (5/<1%)	2,490 (0/0%)	2,490 (0/0%)	2,490 (0/0%)
Silverfish PSU					
Flammulated Owl Habitat (acres/%)	581	580 (1/<1%)	581 (0/0%)	581 (0/0%)	579 (2/<1%)
All Affected PSUs					
Flammulated Owl Habitat (acres/%)	6,704	6,690 (14/<1%)	6,696 (8/<1%)	6,696 (8/<1%)	6,694 (10/<1%)

Number in parentheses is the reduction in habitat acres/percent in habitat area compared to existing conditions.
Source: GIS analysis by KNF using KNF data.

Alternative 3 – Agency Mitigated Poorman Impoundment Alternative

Alternative 3 would not directly affect any flammulated owl habitat and is identical to Alternatives 2 and 4 in this regard. The tailings impoundment would be located 1 mile from the nearest potential habitat and would be unlikely to have any direct effects on that habitat. Disturbance impacts on flammulated owls would be the same for Alternative 3 as Alternative 2, except that MMC would use fixture baffles and directional light sources to minimize ambient light emanating from the mine facilities during operations. Some ambient light would remain, however, and behavior of any nearby flammulated owls could be disrupted. One block of potential habitat is located 1 mile north of Little Cherry Creek. Based on the distance to identified potential habitat and the owl's apparent ability to tolerate moderate levels of disturbance during the nesting season (Linkhart *et al.* 1998), this alternative would have only minor impacts to flammulated owls.

Alternative 4 – Agency Mitigated Little Cherry Creek Impoundment Alternative

There would be no direct effects to flammulated owl habitat due to implementation of Alternative 4, as there is no identified habitat within established limits of the adit, tailings impoundment, or road clearing widths associated with this alternative. Potential effects would be similar to those discussed for Alternative 2, with the addition of fixture baffles and directional light sources to minimize ambient light emanating from the mine facilities during operations and have, at most, minimal effects to flammulated owls in terms of potential disturbance.

Alternative A – No Transmission Line

Impacts on potential flammulated owl habitat caused by the transmission line alternatives are shown in Table 222. Alternative A would not impact flammulated owl habitat.

Alternative B – MMC's Proposed Transmission Line (North Miller Creek Alternative)

Alternative B would reduce the amount of flammulated owl habitat in the McElk, Riverview, and Silverfish PSUs by 14 acres of. These impacts would represent less than 1 percent of the flammulated owl habitat in each PSU (Table 222).

Alternative B would include tree clearing within disturbance boundaries. Removal of large ponderosa pine or Douglas-fir trees and snags that provide potential nesting, feeding, singing, or roost sites could impact flammulated owls (Wright 1996). Given the existing snag levels (see section 3.25.2.2, *Snags and Woody Debris*), the loss of snags providing potential flammulated owl nesting habitat would have minor impacts on this owl. The reduction by 14 acres of potential flammulated owl habitat would be a negligible decrease, with 6,690 acres of habitat remaining in the affected PSUs (Table 222). Once reclaimed and once successional processes were allowed to take place, areas of disturbed flammulated owl habitat could potentially be restored to suitable habitat for this species in the long term.

Alternative B would affect about 8 acres of coniferous forest providing potential flammulated owl habitat on State or private land. The area potentially impacted by alignment of the transmission line would affect portions of two blocks, 325 acres and 91 acres in size. The majority of this area has been previously harvested but would still provide suitable owl habitat with an additional linear opening within its perimeter. Due to the relatively large amount of contiguous habitat still available and the already open nature of these blocks, impacts of Alternative B would be minimal.

Due to lack of suitable habitat, construction of the Sedlak Park Substation and loop line would not affect flammulated owls.

Noise from helicopters during line stringing and from other construction-related activities could disturb nearby habitat temporarily. Owls are more active at night when helicopters would not be operating, and it is doubtful that short-term operations would cause territory abandonment. Disturbance impacts would be short-term and, with the exception of line maintenance activities, would cease after transmission line construction until decommissioning.

Alternative C-R – Modified North Miller Creek Transmission Line Alternative

Alternative C-R would reduce the amount of flammulated owl habitat in the McElk PSU by 8 acres. These impacts would represent less than 1 percent of the flammulated owl habitat in the PSU. The clearing associated with transmission line installation is almost identical to that described for all action alternatives, and effects would be similar (Table 222). The effect on State and private land would be the same in all alternatives. Due to lack of suitable habitat, construction of the Sedlak Park Substation and loop line would not affect flammulated owls.

Alternative D-R – Miller Creek Transmission Line Alternative

Alternative D-R would have the same effects as Alternative C-R.

Alternative E-R – West Fisher Creek Transmission Line Alternative

Alternative E-R impacts on flammulated owl would be the same as Alternatives C-R and D-R in the McElk PSU. There would be an additional 2 acres impacted in the Silverfish PSU. The habitat block affected in the Silverfish PSU is 39 acres. A small sliver of the block (one acre) would be isolated from the larger block, reducing the effective size of the block to 36 acres, roughly the average breeding home range of flammulated owls. This may slightly reduce the suitability of this habitat block, though a range of home range sizes has been observed (Linkhart *et al.* 1998). Due to lack of suitable habitat, construction of the Sedlak Park Substation and loop line would not affect flammulated owls.

Combined Mine-Transmission Line Effects

The effects of the combined mine-transmission line alternatives would be the same as the transmission line alternatives because the mine alternatives would have no effect on flammulated owl habitat.

Cumulative Effects

The Affected Environment section describes the suitable habitat within the analysis area, specifically the warm/dry ponderosa pine and Douglas-fir habitat types within the analysis area. This cumulative effects section summarizes the past actions as well as further describes ongoing and other reasonably foreseeable contributions potentially impacting flammulated owl habitat. As described under the section “Analysis Area and Methods”, the analysis area for cumulative effects to individuals and their habitat consists of the Crazy, Silverfish, McElk, and Riverview PSUs and includes private and State lands crossed by the various transmission line alternatives.

Past Actions

Past actions, including detailed descriptions of previous vegetation and road management activities, are described in section 3.2, *Past and Current Actions*, shown on Figure 50, and listed in Appendix E.

The measure of habitat suitability is alterations to the mapped suitable habitat described in the Affected Environment section of this analysis. Past actions, particularly timber harvest, road construction, and fire-suppression activities, have altered the old growth ecosystems in the analysis area, resulting in a reduction in early and late succession habitats; conditions favoring shade-tolerant, fire-intolerant species; loss of large snags and down wood; increases in tree density; and a shift to a largely mid-seral structural stage (USDA Forest Service 2003b). Timber harvest has occurred in the analysis area since the 1950s and, up until the early 1990s, included regeneration harvest, high grading of large old trees, and loss of snags that resulted in alterations and reduction of flammulated owl habitat. Fire suppression since the early 1900s has generally resulted in stand conversion from open ponderosa pine/Douglas-fir to more shade intolerant species, smaller tree growth and higher stem density, higher canopy cover, and a reduction in productive understory.

Firewood cutting would continue to occur where open roads provide access to old growth habitat, contributing to the removal of snags important to flammulated owls. Continuing development of private lands, including timber harvest, home construction, and land clearing would contribute to losses of flammulated owl habitat in the analysis area. Impacts on flammulated owl on private and State lands would probably be minimal because it is highly fragmented due to high road densities and past timber harvest activities.

No Action Alternative

Alternative 1A would not contribute to cumulative losses of snags and would not contribute to cumulative effects on flammulated owl

Action Alternatives

Ongoing federal actions have been considered and included when formulating the existing condition of this analysis area. Ongoing public firewood gathering has the potential to remove individual snags and other potential nest trees but is not likely to substantively change the character of suitable habitat. Other ongoing activities such as weed spraying, road maintenance, general recreation, and most small mining activities would have negligible impacts to flammulated owl habitat.

The Miller-West Fisher Vegetation Management Project would include intermediate harvest of 1,206 acres, regeneration harvest of about 692 acres, precommercial thinning of 351 acres, and prescribed burning of 2,830 acres of National Forest System lands in the Silverfish PSU. The Coyote Improvement Vegetation Management Project is in the planning stages and would take place within the Crazy PSU. The project would harvest 240 acres to increase stand resiliency to mountain pine beetles. Silverbutte Bugs timber sale is in the Silverfish PSU and would be a small project like Coyote. Timber harvest and other clearing activities planned for the projects will contribute to cumulative losses of snags important to flammulated owls. Activities associated with the projects are expected to retain cavity habitat within KFP-recommended levels for the Silverfish and Crazy PSUs. Also, while treatments associated with the projects will consume some snags and down wood, they also will create snags and down wood by killing live trees. Snags and down wood created in burned areas would provide both feeding and nesting habitat for the flammulated owl.

While the combined action alternatives, in combination with other past, current, and reasonably foreseeable actions, would result in some losses and degradation of flammulated owl habitat in the analysis area, cumulative impacts on overall areas of flammulated owl habitat would likely be minimal and would not likely affect populations in the analysis area. Sufficient habitat would remain within the affected PSUs to support existing populations, and habitat would continue to increase as the recent habitat analysis of forest-wide habitat (Ecosystem Research Group 2012), shows an increase in actual and potential flammulated owl habitat over the next 5 decades. In addition, mitigation associated with combined agencies' alternatives would increase the proportion of designated old growth and promote the maintenance or development of flammulated owl habitat in the analysis area.

Cumulative noise and other human-caused disturbances could occur as a result of the combined action alternatives and other reasonably foreseeable actions. Cumulative disturbance effects could affect individual flammulated owls, but would not likely affect flammulated owl populations in the KNF.

Regulatory/Forest Plan Consistency

Organic Administration Act and Forest Service Locatable Minerals Regulations

36 CFR 228.8 requires that mining operators minimize, where feasible, adverse environmental impacts on National Forest surface resources and to take all practicable measures to maintain and protect fisheries and wildlife habitat that may be affected by the operations. All mine alternatives would comply with 36 CFR 228.8. Transmission Line Alternative B would not fully comply with 36 CFR 228.8. In the proposed action, MMC did not propose to implement feasible measures to minimize effects on the flammulated owl or all practicable measures to maintain and protect wildlife habitat. The agencies' transmission line alternatives would comply with 36 CFR 228.8. The agencies' alternatives would incorporate additional feasible and practicable measures to minimize adverse environmental impacts on wildlife habitat that benefit the flammulated owl, including minimizing clearing in flammulated habitat and implementing a Vegetation Removal and Disposition Plan and Environmental Specifications in the agencies' transmission line alternatives.

National Forest Management Act/Kootenai Forest Plan

The KNF is directed to "identify, protect, and manage" habitat for sensitive species in order to assist in maintaining viable populations. The KFP contains the following goals and direction for sensitive species: "determine the status of sensitive species and provide for their environmental needs as necessary to prevent them from becoming threatened or endangered" (KFP Vol. 1, II-1 #6); All alternatives would meet this KFP direction for the flammulated owl.

All alternatives are consistent with KFP direction for snags, snag replacement trees, and down wood (KFP Vol. 1, II-1 #8 and II-7; Vol. 2, Appendix 16).

Forest Service Management Sensitive Species Statement of Findings

The no action alternatives would not impact individual flammulated owls or their habitat within the analysis area, and would not contribute to a trend toward federal listing or cause a loss of viability to the population or species. ***All combined action alternatives may impact individual flammulated owls or their habitat, but will not likely contribute to a trend toward federal listing or cause a loss of viability to the population or species for flammulated owls.*** This determination is based on: 1) the mine alternatives would have no impact on flammulated owls in the Crazy, McElk, Riverview, or Silverfish PSUs; 2) all transmission line would result in the direct loss of small areas of flammulated owl habitat (8 to 14 acres), but sufficient habitat would remain in the analysis area (6,700 acres) to support a large number of nesting pairs; 3) no active flammulated owl nests were identified in the analysis area during surveys conducted in 2005 (Westech 2005b) implementation of timing restrictions included in the agencies' combined action alternatives would minimize potential impacts on nesting flammulated owls; 6) mitigation measures for the action alternatives and other actions, such as habitat acquisitions and road access changes, could offset some of the impacts on flammulated owl habitat; 7) all combined mine-transmission line alternatives would be consistent with KFP direction to maintain a minimum of 10 percent old growth below 5,500 feet in elevation that may provide flammulated owl habitat; and 8) sufficient habitat within affected PSUs and across the KNF would remain to support existing populations, and habitat would continue to increase as the recent habitat analysis of forest-wide habitat (Ecosystem Research Group 2012), shows an increase in actual and potential flammulated owl habitat over the next 5 decades.

3.25.4.7 Gray Wolf

3.25.4.7.1 Regulatory Framework

In 2011, the USFWS reissued the wolf delisting rule first published in 2009 that delisted biologically recovered gray wolf populations in the Northern Rocky Mountains, including all wolves in Montana (USFWS 2011b). The final rule authorized the State of Montana (FWP) to manage wolves under the state's approved Gray Wolf Conservation and Management Plan. Following delisting, the gray wolf was subsequently added to the Forest Service sensitive species list for a period of 5 years, after which a status review will be made to determine the need to remain on or be removed from that list. The FWP currently manages active harvest of wolves in northwest Montana including within the analysis area.

3.25.4.7.2 Analysis Area and Methods

The Northern Rocky Mountain Wolf Recovery Plan and the Montana Gray Wolf Conservation and Management Plan provide descriptions of wolf ecology, biology, and habitat (USFWS 1987; FWP 2002). The KNF is within the Northwest Montana Recovery Area, one of three wolf recovery areas identified for the Northern Rocky Mountain wolf population (USFWS *et al.* 2004). Information for this recovery area is provided in Bradley *et al*. (2013) and is incorporated herein by reference. The Montana Gray Wolf Conservation and Management Plan identifies the Northwest Montana Recovery Area as Wolf Management Unit 1 (WMU 1). Wolf occurrence data come from recent District wildlife observation records, forest historical data (NRIS Wildlife), other agencies (USFWS, FWP), and Wolf and Wildlife Studies, a private organization.

The analysis area for the gray wolf is described in section 3.25.1, *Introduction*. The analysis area for determination of population trend and contribution toward population viability is the KNF.

The Montana Gray Wolf Conservation and Management Plan Final EIS (FWP 2003) specifies strategies to protect and manage wolf populations in Montana and is based on an adaptive management strategy with more management flexibility granted as the number of breeding pairs in Montana increases above the 15 pair benchmark. Potential management activities cover a range of concerns that include maintaining viable populations of wolves and their prey, resolving wolf-livestock conflicts, and assuring human safety.

Measurement indicators for evaluating effects of the alternatives on the gray wolf are based on the following key habitat components described in the Wolf Recovery Plan (USFWS 1987): year-round prey base, suitable denning and rendezvous sites, and sufficient space with minimal exposure to humans. The rationale for basing the impacts evaluation on these components and the indicators of effects are described in the following paragraphs.

Sufficient Year-Round Prey Base

The condition of the prey base for the gray wolf is evaluated based on KFP management standards and objectives for white-tailed deer and elk. Effects of the alternatives on white-tailed deer and elk are described in section 3.25.3, *Management Indicator Species*. Because the mine alternatives would not affect big game habitat in the Silverfish PSU, the effects of the mine alternatives on prey were evaluated for the Crazy PSU only. As described in section 3.25.3, *Management Indicator Species*, the white-tailed deer was selected as the general forest indicator for the Crazy PSU. Security habitat and HE are among the parameters used to evaluate elk, but not white-tailed deer, habitat quality. For the mine alternatives, effects on habitat supporting big game were evaluated based on effects to cover and forage habitat and ORD. For the transmission line alternatives, effects on elk security habitat and HE were also considered.

Suitable Denning and Rendezvous Sites

Gray wolf den sites are generally greater than 1 mile from open roads and 1 to 2 miles from campsites (USFWS 1987). These sites are normally on southerly aspects, on moderate slopes, within 400 yards of surface water, and at an elevation overlooking surrounding low-lying areas. Sensitivity to disturbance at den sites and subsequent abandonment varies greatly among individual wolves (Thiel *et al.* 1998; Claar *et al.* 1999). Rendezvous sites (resting and gathering areas) are usually complexes of meadows and adjacent timber, with surface water nearby (USFWS 1987). They tend to be situated away from human activity and on drier sites that are slightly elevated above riparian areas (Ibid.). FWP encourages land management agencies to consider the locations of wolf den and rendezvous sites in their planning activities to maintain the habitat integrity of these sites (FWP 2002). Den and rendezvous sites can also be protected by enacting timing restrictions on proposed activities within the den/rendezvous site areas. These restrictions would limit operating periods to the fall or winter seasons when these sites are unoccupied.

Sufficient Space with Minimal Exposure to Humans

Providing sufficient space with minimal exposure to humans can reduce the risk of human-caused mortality to wolves. Human disturbance and accessibility of wolf habitats (*i.e.*, road densities) are the principal factors limiting wolf recovery in most areas (Leirfallom 1970; USFWS 1978, 1987 all in Frederick 1991; Thiel 1978). These components can be generally measured by maintaining ORD standards required by the KFP as well as maintaining any security habitat recommended in the big game habitat recommendations.
